Because the first transgenic flax cultivar was registered in Canada, the emphasis in this section is placed on regulatory process and measures adopted to assess environmental, feed, and food safety of the unconfined release of transgenic plants in Canada, with some relevant references for other countries, mainly United States. Different from the “process-based” approach taken by other countries, Canada is the only country to adopt a “product-based” approach where the regulatory oversight is triggered by the novelty of the product rather than the methods used in its production. Therefore, genetically engineered plants and genetically engineered food products are evaluated as plants with novel traits (PNTs) and novel foods, respectively. The assessment criteria are familiarity and substantial equivalence of PNTs and their products with their nontransformed counterparts that have an established history of safe use. In Canada, the regulation of PNTs and novel foods is coordinated between the Canadian Food Inspection Agency (CFIA), Health Canada, and Environment Canada. In United States, regulation of agricultural biotechnology products is shared between the Animal and Plant Health Inspection Services (APHIS) of the United States Department of Agriculture (USDA), the Environmental Protection Agency (EPA), and

the FDA. The regulatory measures adopted in both Canada and United States are in concert with those developed by the Organization for Economic Cooperation and Development (OECD), the World Health Organization (WHO), and the Food and Agriculture Organization (FAO) of the United Nation (FAO/WHO 2000; OECD 2000a). Confined trials of PNTs in Canada can only be conducted after approval from CFIA and according to the guidelines in Regulatory Directive Dir 2000–2007: Guidelines for the environmental release of PNTs within confined field trials (<http://www.inspection.gc.ca/english/plaveg/bio/dir/dir0007e.shtml>). The environmental safety assessment of PNTs includes the molecular characterization of the PNT in comparison with its conventional counterpart and the environmental impact of the whole plant in comparison with its unmodified counterpart according the criteria in Seed Regulations, Part V (<http://www.inspection.gc.ca/english/plaveg/pbo/ptvreve.shtml>), “Regulatory Directive Dir 94-08: Assessment Criteria for determining environmental safety of plants with novel traits” (<http://www.inspection.gc.ca/english/plaveg/bio/dir/dir9408e.shtml>) and its companion document “Regulatory Directive Dir 94-10: The biology of *L. usitatissimum* L” (<http://www.inspection.gc.ca/english/plaveg/bio/dir/dir9410e.shtml>). Livestock feed safety assessment should be conducted according to the guidelines in “Regulatory Directive Dir 95-03: Guidelines for the assessment of livestock feeds from plants with novel traits” (<http://www.inspection.gc.ca/english/anima/feebet/dir95-03e.shtml>). In order to facilitate the submission of supporting data by developers seeking regulatory approval in both countries, Canada and United States harmonize their respective regulatory requirements for the molecular and environmental characterization of PNTs or genetically engineered plants intended for unconfined release. Details can be found in “Canada and United States 2001 Bilateral Agreement on Agricultural Biotechnology Appendix 1a-Molecular Genetic Characterization Data for Transgenic Plants Intended for Unconfined Release” (<http://www.inspection.gc.ca/english/plaveg/bio/int/appenannex1e.pdf>) and “Appendix II-Environmental Characterization Data for Transgenic Plants Intended for

Unconfined Release” (<http://www.inspection.gc.ca/english/plaveg/bio/int/appenannex2e.pdf>). Food safety assessment in Canada should be conducted according to the Guidelines for the Safety Assessment of novel foods, Volume I and Volume II (http://www.hc-sc.gc.ca/food-aliment/mh-dm/ofb-bba/nif-ani/pdf/e_novele.pdf) developed by Health Canada in concert with internationally accepted practice (OECD 2000b). Additional regulation information and related documents for both Canada and United States can be found at www.agbio.com.

3. FUTURE PROSPECTS

3.1 Expected Products

There are excellent prospects for the further improvement of flax through expected future developments in transgenic research. In relation to agronomic traits, the development of insect resistance based around the successful *Bt* technology would seem feasible and desirable. Flax is susceptible to attack by caterpillars from the *Helicoverpa* family, particularly during bud formation, flowering and capsule development. This genus of pests has been successfully controlled in cotton and corn through transgenic expression of the *Bt* insecticidal protein gene derived from *Bacillus thuringiensis* (Pray *et al.*, 2002) and the technology appears to be broadly acceptable to a wide range of plant species. Other promising agronomic traits, such as increased nitrogen use and water use efficiency (Good *et al.*, 2004; Raines, 2006) once clearly proven are likely to have valuable application in flax in improving productivity and in reducing the impact of abiotic stress.

Breeding for improved resistance to diseases is also likely to benefit from transgenic approaches in the future. The principal economic diseases of flax are flax rust (*M. lini*) and flax wilt (*F. oxysporum*). Resistance to various races of flax rust is controlled by five series of closely linked or allelic genes at loci designated K, L, M, N, and P. It is noteworthy that the first ever cloning of a plant gene for rust resistance was the flax *L6* gene (Lawrence *et al.*, 1995). The subsequent cloning of other resistance genes at the L (Ellis *et al.*, 1999),

M (Anderson *et al.*, 1997), N (Dodds *et al.*, 2001a), and P (Dodds *et al.*, 2001b) loci now enables transgenic breeding for rust resistance in flax, including the possibility of pyramiding resistance genes to multiple races through transgenic creation of additional resistance loci. To date, flax wilt has been effectively controlled in conventional breeding programs by early generation selection in heavily infected wilt nurseries. Genetic factors involved in wilt resistance have been located to particular quantitative trait loci (QTL) regions of the flax genome (Spielmeyer *et al.*, 1998) that may be useful in developing marker-assisted breeding strategies and in eventually cloning the wilt resistance genes. In the future, the development of novel transgenic disease resistance mechanisms may prove useful in flax, particularly for controlling pathogens such as *Mycosphaerella linorum* (pasmus), *Polyspora lini* (browning) and *Sclerotinia* that are currently relatively minor but for which no robust resistance mechanisms have yet been identified.

It is likely that most future transgenic research in flax will be directed toward improvements and further diversification of product quality. Flaxseed is already a source of two types of oil, the traditional high linolenic oil, and the high linoleic, low linolenic oil (Linola[®]) developed for the mass edible oil market. Although primarily used as an industrial drying oil, the traditional high linolenic oil has also found a significant and growing place in the specialty food oils market due to the increasing consumer interest in ω -3 oils. As described above, it is possible that linseed varieties will be developed in the future in which much of this ALA has been further converted to longer chain and more unsaturated ω 3 fatty acids, such as EPA and DHA, by transgenic expression of additional fatty acid desaturase and elongase genes (Abbadi *et al.*, 2004). Such highly unsaturated oils are very unstable and would be at considerable risk of oxidation damage during processing. It may be desirable therefore to genetically enhance the levels of fat-soluble antioxidants such as tocopherols and tocotrienols to protect them from breakdown. A gene for γ -tocopherol methyltransferase (γ -TMT), which converts γ -tocopherol to the more biologically active α -tocopherol form, has been cloned from *Arabidopsis* and over expressed in transgenic plants to produce substantially higher α -tocopherol levels (Shintani and DellaPenna,

1998). However, γ - and δ -tocopherols are much better antioxidants *in vitro*, and they are very important for the oxidative stability of cooking oils. Therefore it is important that any attempts at boosting α -tocopherol levels strike a balance between the different forms of tocopherols. Tocotrienols are another group of important antioxidants, mainly present in the seeds of monocots, that are derived from the condensation of homogenistic acid (HGA) and geranylgeranyl diphosphate catalyzed by HGA geranylgeranyl transferase (HGGT) (Collakova and DellaPenna, 2001). Transgenic expression of barley HGGT in *Arabidopsis* was able to increase the total amount of Vitamin E antioxidants up to 15-fold (Cahoon *et al.*, 2003). Such strategies might, therefore, be applied in the future to impart greater inherent stability on linseed oils engineered to contain EPA and DHA.

The development of low linolenic linseed oil (Linola[™]) paved the way for a wider use of flax seed oils in the food industry (Green and Dribnenki, 1994). The virtual elimination of linolenic acid greatly improved the stability of the oil and enabled it to be used in products, such as margarines and salad oils. However, the high content of linoleic acid in Linola oil prevents its use in industrial frying applications, such as in the food service and snack food industries. Such applications require oils with extremely high stability, which has been provided in the past by the more saturated plant and animal fats and oils, such as palm oil and tallow. Recently, the development of high oleic oilseeds has opened up a large market for commercial frying oils that combine high stability with improved nutrition, and it is possible that new high oleic linseed oils could contribute significantly to this food industry sector in the future. Previous attempts to raise oleic acid by mutation breeding have had only limited success, with 47% being the maximum content reported so far (Rowland and Bhatti, 1990). In contrast, transgenic gene silencing technologies targeting Δ 12-desaturase genes (*Fad2*) have proven successful in blocking the conversion of oleic acid to linoleic acid, resulting in very-high oleic acid levels (80–90%) in several oilseeds, including canola, mustard, and cottonseed (Liu *et al.*, 2002; Stoutjesdijk *et al.*, 2002). The cloning of key fatty acid Δ 9- and Δ 15-desaturases from flax (Jain *et al.*, 1999; Vrinten *et al.*, 2005)

and the deposition of the flax $\Delta 12$ -desaturase sequence in GeneBank (Acc No: DQ222824) provides the sequence information needed to design RNA interface (RNAi) silencing constructs to develop high oleic and high stearate linseed oils.

Genetic engineering of fatty acid composition in flax may also be used in the future to develop novel oils with unique industrial uses. There are many unusual fatty acids present in the seed oils of nonfood plants that would be of considerable value as raw materials for industrial chemical production if they could be produced cheaply in high-yielding oilseed crops such as flax. Most recent attention has focused on those C18 fatty acids that are modified at the $\Delta 12$ position by the addition of epoxy or hydroxy groups, or by the formation of triple bonds (acetylenic) or conjugated double bonds. The introduction of these functionalities into C18 fatty acids is catalyzed by a family of divergent forms of the fatty acid $\Delta 12$ -desaturase (FAD2) enzyme. FAD2-like genes encoding $\Delta 12$ -epoxygenases, $\Delta 12$ -hydroxylases, $\Delta 12$ -acetylenases, and $\Delta 12$ -conjugases have all been cloned (Singh *et al.*, 2005), as well as a further variant responsible for the synthesis of dimorphecolic acid (9-OH-18: $\Delta^{10trans, 12trans}$) in *Dimorphotheca sinuate* (Cahoon and Kinney, 2004). The substrates for these enzymes are either linoleic acid, which is present at high levels in the Linola[®] form of linseed, or oleic acid that can be engineered to high levels by transgenic silencing of the endogenous *Fad2* gene. Thus a variety of transgenic flax plants with oils tailored for particular industrial uses could be developed through the use of genetic engineering – oils that could possibly substitute for petroleum-derived chemicals in the future.

In addition, modification of flax fiber quality through genetic engineering approaches that modify the lignin content in fibers might also be possible in the future. For example, it has been shown in tobacco that down-regulation of the cinnamoyl CoA reductase and cinnamoyl alcohol reductase leads to a reduction in lignin content in fibers (Chabannes *et al.*, 2001). A similar approach if extended to flax could lead to a reduction in lignin levels that would potentially result in softer and stronger flax fiber.

3.2 Expected Technology Developments

3.2.1 Improved transformation efficiency

Optimization of any genetic, physiological and environmental factors relating to either DNA delivery or plant regeneration can contribute to improving transformation efficiency. For *A. tumefaciens*-mediated transformation, these may include optimization through choice of the *Agrobacterium* strain and its resident disarmed Ti plasmid, plant genotype and explant type, selectable marker and selection system, tissue culture medium, and culture conditions influencing plant regeneration. Further improvement in transformation efficiency in flax can be expected when these factors that clearly influence DNA delivery and plant regeneration are coordinately optimized. To date, no comprehensive systematic study has so far been conducted to evaluate the effects of these factors on overall transformation efficiency in flax. For example, although two strains of *Agrobacterium* were used in the experiment of Bretagne-Sagnard and Chupeau (1996) the effect of the *Agrobacterium* strain on transformation efficiency was not examined. Similarly, two flax genotypes were used in the study of Jordan and McHughen (1988a), but the effect of genotype on transformation was not reported. Different explant types, including hypocotyl segments, plastocytes, and anther cultures have been used to regenerate transgenic plants in different laboratories (Dong and McHughen, 1993a; Ling and Binding, 1997; Chen and Dribnenki, 2003). In one study, use of anther cultures as the explants had significantly higher transformation efficiency than use of hypocotyl segments as the explants (Chen *et al.*, 2008). The demonstrations of the effect of the preculture period when hypocotyl segments are used as the explants (McHughen *et al.*, 1989) and of the effect of anther age on success of anther culture (Chen and Dribnenki, 2003) are two examples in flax that show the impact of physiological conditions of the explants on transformation efficiency. One of the most critical opportunities for increasing transformation efficiency is in finding ways to promote regeneration of plants from transformed cells. Usually, the percentage of flax explants producing transgenic shoots has been much lower than the percentage of explants

showing transgene (*GUS*) positive cells, indicating that many successfully transformed explants fail to regenerate shoots. Further modification of the media in combination with a well-balanced selection regime may help to improve this aspect of transformation efficiency in the future.

3.2.2 Alternative selectable markers and production of selectable marker-free plants

The function of (positive) selectable markers is to confer the selective advantage to transformed cells over nontransformed cell and thereby facilitate the recovery of the small portion of transformed cells/plants. The selectable marker genes that have mainly been used in flax transformation have been antibiotic resistance genes, i.e., *nptII*, *hph*, and *aadA* (McHughen, 1989; Bretagne-Sagnard and Chupeau, 1996; Chen and Dribnenki, 2003), which have raised some public concerns. Though transgenic flax plants containing the *nptII* gene have been formally approved for commercial release, herbicide resistance genes may have a better chance for public acceptance of the genetically engineered products. The phosphinothricin N-acetyltransferase (*pat*) or bialaphos resistance (*bar*) genes that confer resistance to phosphinothricin have been used successfully to regenerate transgenic flax plants (McHughen and Holm, 1995a, b). However, there are no reports of using either resistance to glyphosate, by expression of a mutated form of *epsp* synthase from petunia (Jordan and McHughen, 1988a) or resistance to sulfonylurea, by expression of a mutated form of *als* gene (McHughen, 1989), as the selectable marker in flax transformation. With some optimization of the transformation protocol it should be feasible to directly use glyphosate or sulfonylurea as the agent to select herbicide tolerant transgenic plants.

Alternative selectable marker systems to antibiotic and herbicide resistance have been developed and successfully employed in some transformation systems. These include phosphomannose isomerase (Joersbo and Okkels, 1996), xylose isomerase (Haldrup *et al.*, 1998), and deoxyglucose-6-phosphatase (Kunze *et al.*, 2001). In these systems, the presence of metabolite analogues (e.g., mannose, xylose, and deoxyglucose) as the

selectable agents favors the growth of transformed cells rather than killing nontransformed cells. Transformed cells expressing the selectable marker genes are able to convert the metabolite analogs into the metabolites that can be used to support cell growth and therefore acquire growth and development advantages on medium containing the metabolite analogs. Therefore, the transformation efficiency could be higher than in antibiotic or herbicide selection schemes where substances released from dead cells could be detrimental to the growth and regeneration of transformed cells into plants (Joersbo and Okkels, 1996). However, these alternative selectable marker systems have not been evaluated in flax. Alternatively, scorable markers can be used to visually differentiate transformed cells and shoot without adding any chemicals to the regeneration medium. These types of scorable markers may include *gfp* gene from jelly fish (*Aequorea victoria*) encoding green fluorescence protein and *ipt* gene encoding for isopentenyl transferase that catalyzes cytokinin synthesis and thereby causes transgenic cell proliferation and differentiation into shoots. The expression of *gfp* enables the identification and isolation of transformed cells at earlier stage of development (Ahlandsberg *et al.*, 1999). Expression of *ipt* in transformed cells results in the regeneration of shoots with “shooty” phenotype, i.e., lack of apical dominance and roots (Endo *et al.*, 2001). Transgenic plants with normal phenotype can be recovered by utilizing the site-specific recombination R/RS system with or without inducible system to remove the *ipt* gene or restrict expression of *ipt* gene (Endo *et al.*, 2002).

In order to simplify the regulatory process and improve public acceptance of genetically engineered products, elimination of selectable marker genes, either antibiotic or herbicide resistance or scorable marker genes, and any foreign genetic elements in final products would be most desirable. Different strategies developed so far include site-specific recombination (Dale and Ow, 1991), homologous recombination (Zubko *et al.*, 2000), transposition (Goldsbrough *et al.*, 1993), and co-transformation of selectable marker gene and gene of interest as separate transgenes to enable segregation of marker-free transgenic plants in progeny generations (Depicker *et al.*, 1985; Daley *et al.*, 1998). To overcome the problem of large size binary vector encountered with two

sets of T-DNA border sequences with a single plasmid in co-transformation, a double right border (DRB) binary vector carrying two sets of right border sequences flanking a selectable marker gene followed by a gene of interest and one set of left border was developed (Lu *et al.*, 2001). Using this type of vector to transform rice, approximately 36–64% of the primary transformants produced selectable marker free progeny (Lu *et al.*, 2001). Recently we have produced over 100 transgenic flax plants using this strategy and evaluation for the presence of marker-free plants in their progeny is in progress (Chen *et al.*, 2008).

3.2.3 Improved transgene expression

The current transformation strategy is to produce sufficient number of transgenic plants in order to select transformation events that have desired level of expression of the gene of interest. This strategy is labor intensive and costly. Of the different strategies that have been proposed to minimize the variation of transgene expression in plants (Butaye *et al.*, 2005), the most feasible approach is to use methods that favor the production of transgenic plants with single copy of transgene insert, since high levels of expression of transgenic traits are reproducibly correlated with single copy of transgene (Hobbs *et al.*, 1993). *Agrobacterium*-mediated transformation generally produces a high frequency of transgenic plants with preferential integration of defined T-DNA's into transcriptionally active regions of chromosome, exclusion of vector DNA, few rearrangements, and stable expression of transgene over generations (Gelvin, 2003). In contrast, microprojectile bombardment and other direct transformation methods often result in the random integration of multiple copies of transgenes into the genome, with possible fragmentation and rearrangements of the gene (Kohli *et al.*, 1998).

All genetic, physiological and environmental factors influencing transformation efficiency can potentially affect transgene copy number. For *A. tumefaciens*-mediated transformation, these factors may include the optimization in selection of *Agrobacterium* strain and its resident disarmed Ti plasmid, plant genotype and explant type, selectable marker and selection scheme, tissue cul-

ture medium, and culture conditions influencing plant regeneration.

The strategy to generate single copy transformation events using cre/lox site-specific recombination system has been developed and successfully used in wheat transformation (Srivastava *et al.*, 1999). Design of vectors with a negative selectable marker located “left” of the left border on the binary plasmid should help to generate more transgenic plants without plasmid backbones since sequences from beyond the left border are incorporated into transgenic plants due to the occasional overriding of left border signal (Martineau *et al.*, 1994).

3.2.4 Seed-specific promoters

Identification of seed-specific promoter is crucial for any transformation projects aiming at modifying seed quality traits. Transgenic flax plants with the unknown seed protein (USP) promoter from *Vicia faba* showed persistent expression between 5 to 40 days after flowering (daf) whereas plants with another seed-specific promoter LeB4 from *Vicia faba* or seed-specific KCS promoter of β -ketoacyl-CoA synthase gene from *Brassica napus* had expression between 11 to 40 or 14–40 daf, respectively (Drexler *et al.*, 2003). The expression levels of transgene under the control of either USP or LeB4 promoter from *V. faba* were 100 to 1000 times higher than that under control of either KCS or napin promoters from *B. napus* (Drexler *et al.*, 2003). In a more recent study, conlinin promoter from flax was found to have the expression level high enough to be useful for seed modification purpose, whereas the *Arabidopsis* FAE and *B. napus* napin promoters had low levels of expression during seed development (Caillot *et al.*, 2006).

3.2.5 Transfer of multigene constructs

Transfer of multiple genes into plants is necessary for the stacking of transgenes specifying different traits and for the introduction of multiple enzymes constituting complex metabolic pathways, such as biosynthesis of LC-PUFAs. This can be achieved by sequential transformation with individual transgenes (Qi *et al.*, 2004), or by recombination through crossing of independently transformed

lines. These two strategies both require an additional generation to determine the expression level of the first transformation and to identify the desirable event for subsequent transformation or crossing. Alternatively, multiple transgenes could be cloned into the same vector under the control of independent promoters. Using this approach a binary vector containing a $\Delta 6$ -desaturase, a $\Delta 6$ -elongase, and a $\Delta 5$ -desaturase each under the control of USP promoter was successfully used to transform flax to produce long-chain $\omega 6$ and $\omega 3$ polyunsaturated fatty acids (Abbadi *et al.*, 2004). More recently, a binary vector containing nine genes under the control of various promoters was used to transform *Brassica juncea* to produce DHA (Wu *et al.*, 2005).

3.3 Risks and Concerns

An increased array of new quality types in crops in the future as a result of the application of gene technology should provide growers with enhanced flexibility in their crop production and marketing decisions. Some new products will probably represent such a significant quality improvement that they become the new standard for the commodity itself, while others will become established only as higher-value specialty types with much smaller markets than the traditional commodity. Capitalizing on the opportunities provided by this expanded range of diversified quality types presents a number of significant challenges for crop production systems and for supply chain management.

3.3.1 Maintaining variety integrity

The need for variety integrity is likely to be more important with the introduction of transgenic (genetically modified, GM) crops, particularly those with new output traits, than is currently the case with traditional crop varieties. Although strict measures are already taken during planting seed production to minimize the risks of cross contamination with other varieties, the consequences of very low admixture levels are generally not significant with traditional varieties. Within quality types of a species the main consequence is the potential for dilution in the overall agronomic performance of superior varieties,

which is probably insignificant with low levels of contamination. However, the consequences of contamination between quality types can be much greater because of the possible failure to meet end product quality specifications. With transgenic crops the consequences of contamination are much more serious, firstly because of the strict requirements for regulatory approval for release of transgenic plants and plant products, and secondly because of the much more significant genetic and compositional differences that transgenic crops will have from their traditional counterparts.

It is, therefore, particularly important to ensure that a GM variety that is being grown either experimentally in prerelease field trials, or commercially for a particular market, where it is approved for release, does not contaminate planting seed or commercial grain of other varieties that are destined for markets where the transgenic trait is not approved for release. This is an important consideration because of the significant international movement of planting seed during multiplication and because of extensive grain trade between countries under different regulatory jurisdictions. The extent of concern for this aspect will be related to the degree of contamination tolerance that is allowable in the market. During the early phases of introduction of transgenic crops regulatory approvals are generally not available in all potential markets, and there is also considerable niche marketing of GM-free products. Both circumstances currently require zero tolerance for GM contamination. As an example of the possible pitfalls, some canola growers in Europe had to destroy crops of a non-GM canola variety when DNA testing revealed that it contained plants carrying the glyphosate resistance transgene that was not approved for release in Europe. The contamination was believed to have occurred during pedigree seed production of the variety in Canada, presumably either by outcrossing with nearby Roundup Ready[®] canola varieties or by physical seed contamination during production, harvest, or subsequent seed handling. This example highlights the difficulty in guaranteeing 100% purity in agricultural systems and underlines the need for introduction of practical minimal tolerance levels in order for conventional and transgenic crops to coexist.

Initial concerns for varietal integrity have mainly centered on ensuring that transgenes that

confer traits that could have agro-ecological consequences, such as herbicide tolerance, do not transfer to or contaminate varieties that do not contain these traits. This is important because of the desire to deploy such genes in a controlled manner to minimize the risk of them transferring to other varieties or related weed species. It is also necessary to avoid the possible unintended development of genotypes that carry resistances to multiple herbicides. The regulatory approval process for release of such GM varieties may require the proponent to develop approved crop management plans that, among other requirements, address the need to contain the transgenic traits within the GM variety. In the longer term this issue will also become particularly important for GM varieties that carry output traits. In some cases, such as where both the conventional and GM varieties are destined for similar food markets, the practical consequences of contamination will be similar to those that exist between conventionally bred quality variants. However, in the case of future GM varieties producing nonfood products there may be serious adverse consequences associated with even a low level of contamination. For example, it will probably be unacceptable for edible flaxseed destined for human consumption to have even low-level contamination from flaxseed that contains, for example, a novel industrial fatty acid that may be potentially toxic to humans, or a pharmaceutical peptide that should be tightly controlled in its human applications. In these cases, it will be extremely important to maintain strict varietal integrity.

Minimizing the risk of gene transfer between industrial and food crops can be achieved more easily in highly self-pollinated crops than in open-pollinated crops. It would therefore seem more advantageous to develop specialty industrial fatty acid products in self-pollinated oilseed crops such as flax or soybean, than in outcrossed crops such as sunflower or rapeseed. However, because this may not always be possible on technical or economic grounds, scientists are already conceiving of genetic methods by which novel varieties can be prevented from intercrossing with other varieties. It may be possible to develop systems that ensure that varieties with particular attributes that require segregation are reproductively isolated from all other varieties in the same way that different plant species are

unable to interbreed. Such systems could be valuable ways to provide certainty that herbicide tolerance genes would not transfer to related weed species, and that industrial product quality traits do not transfer to food-grade varieties.

3.3.2 Identity preserved crop production

Even with the strictest attention to detail in maintaining the integrity of varietal planting seed, there is still potential for cross-contamination of grains during commercial crop production, storage, handling, and processing. For crops that have modified output traits and that therefore need to be channeled toward particular markets or specialty uses, it will be necessary to implement strict procedures for segregation and identity preservation during production and processing in order to capture the added-value associated with the particular output trait. In some markets it may be commercially advantageous to market crop products based on their non-GM status, particularly during the early stages of introduction of GM crops. In this case, the non-GM status can be regarded as a type of output quality trait, and identity preservation may be necessary in order to be able to guarantee this status to the final customer. In contrast, in most circumstances it should not be necessary to maintain segregation and identity preservation for GM varieties that carry only input traits and produce end products that are substantially equivalent to the conventional variety.

Identity preservation is simply a system of crop supply chain management that preserves the identity of the source and nature of the product. It is not a new concept in agriculture since it is already in use for the production of a number of non-GM specialty crop types. Furthermore, the seed industry routinely undertakes identity preservation in the production of varietal planting seed. This is a relatively straightforward process in situations of low volume specialty crops grown either in-house or under contract, where the owner of the product has full control of the production process, takes delivery of all of the final grain, and usually manages its passage through the primary processing stages of the supply chain. In this situation, the implementation of audit trails and quality control monitoring is relatively easy.

However, it is a much harder task for high-volume products that are widely grown and marketed openly by growers because it may be difficult to ensure that all growers comply with all the grain production and handling procedures necessary to ensure product purity. In this situation, quality testing needs to be implemented at all initial grain receival points and be completed prior to any aggregation of grain.

When the product is a grain with particular new quality attributes, there will be incentive throughout the supply chain to maintain the identity preservation in order to achieve the price premiums for the product at each stage. However, when the product does not have any different processing properties or pricing structure, such as for GM grain carrying only input traits, there is greater potential for identity preservation to fall down. This occurred when US processors and retailers had to withdraw a number of corn-based food products from sale after DNA testing revealed that they contained corn carrying the Aventis StarLink[®] insect resistance trait, which had been granted approval by regulatory authorities for nonfood use only. Aventis had introduced a stewardship program to ensure that StarLink[®] corn would only be used for industrial purposes. However, the StarLink[®] trait appears to have been found in other conventional corn varieties developed by StarLink[®]-licensed corn seed producers, thereby escaping the dedicated marketing channels. This incident demonstrates the greater difficulty in implementing fully effective identity preservation and supply segregation in situations where traits are licensed to multiple seed producers for crops that are to be sold on open markets, compared to that within closed-loop contract production and marketing systems.

The need for effective identity preservation, combined with proprietary ownership of many quality trait technologies, should lead to a significant increase in contract production and closed-loop marketing. This type of supply chain management has significant additional costs that will need to be recouped in premiums for the final product to be economically viable. The cost of identity preservation will vary depending on the precise circumstances of the crop and the range of products derived from it, the uses to which they are put, the tolerances and specification set, and the

sophistication of the distribution system. However, initial experience indicates that the cost range is generally in the order of 5–10% of the price of the grain (Buckwell *et al.*, 1998). Identity preservation will only be economically viable for products that have end market price premiums significantly in excess of this amount. This requirement will be a primary factor in determining the commercial success of new product quality types developed by gene technology, as well as in determining the long-term sustainability of the current niche markets for non-GM products that offer no other advantage.

1. INTRODUCTION

1.1 History, Origin, and Distribution

Sesame (*Sesamum indicum* L. syn. *S. orientale* L.) is one of the oldest cultivated crops known to man. It was a highly prized oilseed in the ancient world because of its resistance to drought, the ease to extract oil from seeds and the high stability of the oil (Langham and Wiemers, 2002). Archaeological remains of sesame dating back to 5500 BC have been found in the Harappa valley in the Indian subcontinent (Bedigian and Harlan, 1986). The origin of the crop has been a major subject of discussion, with proposals for an African or Indian domestication. Based on various lines of evidence including cytogenetics, biochemical composition, nuclear DNA marker comparisons, and cultural history to name a few, Bedigian (2003, 2004) has concluded that this species was first domesticated in the Indian subcontinent. From there, it spread to Africa, the Mediterranean, and the Far East, and into the Americas following trade routes. Today sesame is widely grown in China, Japan, Korea, Turkey, India, the United States, South America, and parts of Africa as an oilseed crop.

1.2 Botanical Description

1.2.1 Taxonomy and cytogenetics

The genus *Sesamum* belongs to the family *Pedaliaceae*, with about 16 genera (Nayar, 1995). A comprehensive taxonomic characterization of the species within this genus has yet to be accomplished. So far, about 35 species have been identified of which 22 are endemic to Africa and only 5 are found in Asia. There are three cytotaxonomic groups with $2n = 26$, $2n = 32$, and $2n = 64$ within the genus. Cultivated sesame along with *Sesamum alatum*, *Sesamum capense*, *Sesamum schenckii* and a few others belong to the first group. There is limited cross compatibility among the species, especially due to the differences in chromosome numbers (Nayar and Mehra, 1970; Nayar, 1995). Owing to the existence of hybridization barriers, it has been difficult to transfer desirable characteristics such as drought, pest, and disease resistance from wild relatives into *S. indicum*.

1.2.2 Growth habit

Sesame is an erect herbaceous annual crop that grows to a height of 0.4–2 m. The plants are

often highly branched, but some varieties are relatively unbranched. Stems are square with grooves. Leaves are hairy on both sides with variable shape (ovate to lanceolate) and size, and may be opposite or alternate. Pale purple to white bell-shaped flowers begin to develop at leaf axils within 6–8 weeks after planting. A single flower is produced at each leaf axil starting from the lower axils and the plant continues blooming until the uppermost flowers on the stem are open (Day, 2000a). Multiple flowering is common in varieties with opposite leaves (Oplinger *et al.*, 1990). Sesame is predominantly self-pollinated, although cross-pollination by insects is common (Pathirana, 1994). The fruit is an oblong capsule, 2–7 cm long, containing 50–100 or more seeds. The seeds are oval and may be white, yellow, red, brown, or black in color. The seeds mature 4–6 weeks after fertilization. Sesame grows indeterminately, producing new leaves, flowers, and capsules at the same time as long as the weather conditions permit. The growth cycle is completed within 70–180 days depending on the variety and growth conditions.

1.2.3 Growth conditions

Sesame is well adapted to high growth temperatures of up to 40 °C and drought. However, it requires adequate moisture during sowing and early growth stage, and at least 300–400 mm of rainfall per season for reasonable yields. Late rainfall in the season prolongs growth and increases seed loss due to shattering. The crop can grow on a range of soil but performs best on well drained, fertile medium textured soils with neutral pH. It has a very low tolerance to salinity and is highly susceptible to waterlogging.

1.3 Economic Importance

India and China are the world's largest producers of sesame, followed by Myanmar, Sudan, Uganda, Nigeria, Pakistan, Ethiopia, and Bangladesh (FAOSTAT, 2005). In 2005, the total world production was about 3.3 million tons grown on 7.4 million hectares. Sesame currently ranks sixth in the world production of edible oil seeds (Table 1) and twelfth for vegetable oil produced (Table 2).

Table 1 World production of major oil seeds in 2005^(a)

Oil crops	Production (million tons)
Soybean	214 347 289
Rapeseed	47 161 378
Cotton seed	41 132 246
Groundnut (in shell)	35 865 389
Sunflower	30 944 162
Sesame	3 325 679
Linseed	2 801 277
Castor bean	1 393 812
Tallowtree	870 000
Safflower	773 427
Mustard	621 023

^(a)Source: <http://faostat.fao.org/>, FAOSTAT (2005). Last updated September 2006

The low ranking of sesame in the vegetable oil market may be attributed to several factors including low seed yield, difficulty to mechanize harvesting, and strong competition from more cheaply produced vegetable oils, such as palm and coconut oil. In addition, there has been limited breeding effort, largely due to the fact that it is mainly produced in resource-poor developing countries that cannot sustain long-term improvement programs for the crop. The establishment of sesame as a major crop has been extremely slow considering its long history. The use of modern plant breeding knowledge and new technologies could benefit research aimed at improving the crop (Ram *et al.*, 1990).

Table 2 World production of vegetable oils in 2003–2004^(a)

Oil	Production (million tons)
Soybean	30 014 000
Palm	28 158 800
Rapeseed	12 566 900
Sunflower	9 949 790
Groundnut	5 900 250
Cottonseed	3 547 180
Coconut	3 325 890
Palm Kernel	3 262 010
Olive	2 982 510
Maize	2 083 850
Rice bran	1 407 700
Sesame	1 067 180
Other crops	5 194 961

1.3.1 Uses of sesame

Sesame is grown primarily for its nutritious seeds that are rich in linoleic acid, protein, and calcium as well as vitamin E, and small quantities of vitamins A, B1, and B2. Nearly 70% of the world's sesame seed is processed into oil and meal while the remainder is channeled to food and confectionery industries (Morris, 2002). The oil is mainly used in cooking and salad, and for making margarine. It is also used in cosmetics preparations, pharmaceutical products, paints, soaps, and insecticides (Ashri, 1989, 1998). The meal left after oil extraction contains 35–50% protein and makes a rich feed for poultry and livestock.

Sesame seed is used on bread, buns, cookies, health snacks, and as an additive to breakfast cereal mixes. The seeds may be eaten whole either raw or roasted and salted, or mixed with lemon and honey, but are often ground into paste (Tahini), which may also be sweetened with sugar (Halva). Sesame seed is used as an ingredient in many recipes, added whole or pounded. In Africa, the paste is used as a spread and in preparing soups and sauces.

1.3.2 Economic and nutritional attributes of sesame

Sesame has a relatively superior oil quantity as well as quality in comparison to many major oil crops. The oil content ranges from 34% to 60% but is mostly about 50% of seed weight (Ashri, 1989, 1998). Values of up to 63.2% have been reported in some varieties (Baydar *et al.*, 1999; Uzun *et al.*, 2002). Both genetic and environmental factors influence the oil content in sesame. Late maturing cultivars are reported to have higher oil content than early ones (Yermanos *et al.*, 1972). Uzun *et al.* (2002) observed that indeterminate cultivars accumulated more oil than determinate ones. Variation also occurs between capsules at different positions on the same plant, such that seeds from the basal capsules on the main stem contain more oil than those located toward the apex and on side branches (Mosjididis and Yermanos, 1985; Muthuswamy and Thangavelu, 1993). Black seeded cultivars often have lower oil content than brown or white seeded ones, indicating a possible linkage between oil content

and seed coat color. Kamal-Eldin and Appelqvist (1994a) have attributed the low oil content in black seeded sesame to a high amount of crude fiber in the seed coats. Black seed coats are usually thicker than lighter colored ones.

The *Sesame* genus has limited variability in the seed fatty acid proportions (Kamal-Eldin *et al.*, 1992). The variation in the seed fatty acid composition is mainly with the oleic and linoleic acids among the different cultivars of sesame worldwide (Yermanos *et al.*, 1972; Brar, 1982; Baydar *et al.*, 1999). The oil contains four major fatty acids namely, palmitic, stearic, oleic, and linoleic acids, along with small quantities of vaccenic, linolenic, arachidic, behenic, and eicosenoic acids (Weiss, 1983; Kamal-Eldin *et al.*, 1992; Ashri, 1998; Were *et al.*, 2001). Oleic and linoleic acids occur in nearly equal amounts, constituting about 85% of the total fatty acids.

Cultivars with exceptionally high (>60%) oleic or linoleic acid are rare (Baydar *et al.*, 1999). Uzun *et al.* (2002) found differences in stearic, oleic, and linoleic acids between determinate and indeterminate cultivars. Determinate cultivars generally have higher stearic and oleic acids, and lower linoleic acid compared to indeterminate ones. Capsule position on the plant also affects the relative quantities of the fatty acids; palmitic, stearic, and oleic acids tend to increase up the stem while linoleic acid decreases (Brar, 1977). The fatty acid composition is strongly influenced by environmental factors. Linoleic acid content has been reported to increase under cool growing conditions (Uzun *et al.*, 2002).

The fatty acid composition is a major determinant of edible oil quality. Oils having high oleic acid content, in combination with low quantities of saturated and polyunsaturated fatty acids (PUFAs) are commercially and nutritionally desirable. Saturated fatty acids are associated with high risk of heart disease (Jakobsen *et al.*, 2004). Whereas PUFAs are known to be beneficial for human health, high PUFA quantity in edible oil is undesirable as they are readily oxidized yielding products that are potentially harmful to human health, and which give off-flavors and odors to foods. Sesame oil has a low level of saturated fatty acids ($\leq 15\%$) and approximately equal quantities of mono- and polyunsaturated fatty acids. The oil is nutritionally valuable as a source of linoleic acid that is essential to man.

Despite having a high content of linoleic acid, sesame oil is unusually stable to oxidation compared to other vegetable oils with a similar fatty acid composition. This feature is attributed to antioxidant activities of sesamol and sesaminol together with tocopherols present in the oil (Kamal-Eldin and Appelqvist, 1994b; Suja *et al.*, 2005). A combination of the high stability and a nutritionally acceptable fatty acid composition contributes significantly to the excellent oil quality, making it a high-value edible oil.

Recent studies have shown that sesame oil is beneficial in lowering cholesterol levels and hypertension (Sankar *et al.*, 2004; Frank, 2005), and reducing the incidence of certain cancers (Miyahara *et al.*, 2001). These health enhancing effects of sesame oil are explained by the low level of saturated fatty acids as well as the activity of antioxidants mainly sesamin. Sesamin is known to enhance the availability and functioning of vitamin E (tocopherol) (Ghafoorunissa *et al.*, 2004). An elevated concentration of γ -tocopherol in the blood is associated with reduced risk of heart disease and some cancers, such as those of the upper gut. Thus, sesame oil could be beneficial for enhancing health by improving the vitamin E levels in the body (Frank, 2005).

1.4 Traditional Breeding

1.4.1 Breeding objectives

Although sesame is one of the most important oil crops in the world, it has received less breeding efforts (Ashri, 1987). Its commercial production and extension is constrained by low yields, pests and diseases, shattering of seeds from mature capsules, and lack of uniform maturity of capsules (Langham and Wiemers, 2002). Other breeding challenges include bitter flavor or principles that limit market for whole seed (Oplinger *et al.*, 1990) and drought tolerance since sesame is generally grown in areas with rainfall of less than 600 mm per annum.

The major breeding objectives of sesame were summarized by Ashri (1987), as shown below:

- Improved seed retention in the capsules.
- High seed yield.
- Resistance to diseases and pests.

- Uniformity in plant type and agronomic characteristics including uniform capsule maturity.
- Low amount of bitter principle in seeds.
- High number of capsules/leaf axil.
- Good adaptation to varying environments (e.g., drought resistance).

1.4.2 Breeding strategies and tools

Sesame breeding efforts have in the past utilized naturally occurring variations and induced variations through intra- and inter-specific hybridization or mutations (Lee and Choi, 1985; Pathirana, 1992; Dharmalingam and Ramanathan, 1993; Prabakaran *et al.*, 1995).

Sesame shows great range of natural genetic variation in many of its characteristics (Ashri, 1989) including days to flowering, plant height, branching, corolla color, number of flowers per leaf axil, capsule length and shape, number of carpels, capsule hairiness, seed size and length, early maturity, resistance to drought, diseases and pests, shattering resistance, and oil content. The presence of a number of such easily recognizable simply inherited characters makes it possible to identify crossed progenies and may speed up crop improvement (Weiss, 1983).

Controlled crossing is simple and each cross can produce 50 or more seeds making it easy to breed for improved varieties. Sesame is considered as a self-pollinating crop (Weiss, 1983) although varying amounts of natural outcrossing ranging from less than 10% (Pathirana, 1994) to over 50% (Van Rheenen, 1968; Uzo, 1977) have been reported depending on local conditions and insect populations. Thus traditionally an isolation distance of 180–360 m has been used to maintain seed purity (Weiss, 1983).

1.4.3 Breeding for diseases/pests resistance

Sesame is affected by a number of diseases including angular leaf spot (*Cercospora sesamicola*), white leaf spot (*Cercospora sesame*) (Nyanapah *et al.*, 1995), *Alternaria* leaf spot (*Alternaria sesami*) (Ojiambo *et al.*, 1999), stem rots, powdery mildew (*Oidium* spp.), bacterial diseases (*Pseudomonas sesami*) (Weiss, 1983; Oplinger *et al.*, 1990), and wilts (*Fusarium* spp.).

Although most of these diseases are controlled by cultural practices and fungicides (Oplinger *et al.*, 1990), some of them have been managed through resistance breeding. This is possible since natural genetic variation for resistance exists for some of the diseases. For example, Nyanapah *et al.* (1995) observed variation in resistance to angular leaf spot (*C. sesamicola*) and white leaf spot (*C. sesame*) among Kenyan cultivars. Cultivars SIK 031 and SIK 013 were resistant to white leaf spot, while SIK 031 and SPS 045 were resistant to angular leaf spot (Nyanapah *et al.*, 1995). Breeding programs that incorporate some of these germplasm can produce high yielding cultivars even in areas where these pathogens are a constraint.

Using natural variation, selection breeding has been partially successful in producing varieties that are resistant to bacterial leaf spot (*P. sesami*), *Fusarium* wilt and phyllody (Weiss, 1983). At present there are no totally resistant cultivars to these major diseases. Resistance to *Sclerotinia*, *Fusarium* (El-Shazly *et al.*, 1999) and *Rhizoctonia* (Serry, 1976) exists but these are not yet incorporated into commercial varieties. Phyllody caused by mycoplasma-like-organism (MLO) transmitted by *Orosius albicinctus* is one of the most destructive diseases of sesame in India and Burma (Nakashima and Murata, 1993).

The major damaging pests of sesame include aphids, spider mites, white flies (*Bemisia argentifolii*), jassids, sesame flea beetle (*Alocypha bimaculata*), leafroller caterpillar (*Antigastra cata-launalis*), and army worms (*Cupis unipuncta*) (Langham and Wiemers, 2002). Most of these insect-pests may be controlled by chemical sprays; however, in sesame this is not economical. There are some lines of sesame varying from tolerance/resistance to extreme susceptibility to green peach aphid (*Myzus persicae*) and cabbage lopper (*Pieris rapae*) but resistance/tolerance to these insects are yet to be incorporated into commercial varieties. However, some of the wild species have been found to have resistance to root rot and *Antigastra* spp. *Sesamum radiatum*, *Sesamum laciniatum* and *S. alatum* show resistance to *Antigastra*. *Sesamum malabaricum* is also resistant to this pest. Under the All India Coordinated Research Project on Sesame and Niger, several workers have attempted wide crossing of *S. indicum* with wild *Sesamum* species

and successful interspecific derivatives have been generated (Prabakaran, 1996).

1.4.4 Breeding for resistance to shattering

High harvest losses due to seed shattering in dehiscent varieties continue to limit domestic production of sesame in many countries. According to Langham and Wiemers (2002), as much as 50% of the seeds could be lost due to shattering in certain environments. In most indeterminate sesame cultivars, there is a continuum from mature seed to immature seed on the plants. For these cultivars, early capsules dry, open, and lose seeds before or during harvesting.

Shattering makes harvesting operation difficult and costly, since the cost of manual harvesting constitutes about 70% of the total cost (Khidir, 1972). Production is constrained by shortage of labor during critical harvesting period, since 99% of sesame is harvested manually (Langham and Wiemers, 2002).

Mutants with indehiscent character (shattering resistance) have been developed from mutation breeding using γ -ray irradiation (Çağırhan, 1996, 2001). Unfortunately this so-called *closed capsule* or *idid* genotype is associated with undesirable properties such as semi-sterility, cupped leaves, twisted stem, short capsules, and low yields (Langham and Wiemers, 2002). In addition, plant lines with the indehiscent character are hard to thresh (Day, 2000b). The indehiscence is governed by a single recessive gene and Uzun *et al.* (2003) have developed a molecular marker that is linked to the *closed capsule* mutant trait. This marker allows the easy identification of the indehiscent trait in breeding programs to integrate it into desired genetic backgrounds.

Through intensive breeding program by the Sesaco Company, USA, shattering resistant types free of the undesirable traits have been obtained (Langham and Wiemer, 2002). Shattering resistant mutants that are indehiscent have been extensively used by breeders in the United States to produce high yielding varieties with as low as 5% shattering. Such varieties are suitable for mechanized production of sesame. Mechanical harvesting of sesame reduces the labor cost, and is preferred for increased acreage

(Langham and Wiemer, 2002) and seed yield per acre.

1.4.5 Breeding for increased seed yield

The major limitation to sesame growing/production is the highly variable and low seed yield. The world average is only about 340 kg ha⁻¹ compared to 2250 kg ha⁻¹ obtained under good crop management (Brigham, 1985, 1987). One of the major contributing factors to low yields in sesame is low breeding attention (Pathirana, 1995) and lack of specific research on yield structure as a basis for progress in sesame breeding (Baydar, 2005).

Approaches used for increased seed yield vary greatly from simple plant selection (Kinman and Martin, 1954) to hybrid cultivar development (Quijada and Layrisse, 1995). They have been selecting plants with extra numbers of capsules per axil, extra number of carpels per capsule, and moderate branching habit. The overall strategies in breeding for this trait have largely involved introductions accompanied by mass or single plant selections (Pathirana, 1995; Baydar, 2005), pedigree or hybridization programs to generate new variation and/or combine specific traits, particularly when genetic variation for yield is exhausted within local populations due to continuous selection (Ashri, 1989). While selecting segregating populations, Pathirana (1995) found bulk breeding method to give quick results.

Heterosis has been reported for sesame for several agronomic traits including seed yield (Mishra and Sikarvar, 2001; Sankar and Kumar, 2001; Duhoon, 2004). Several sesame hybrids showing significant heterosis for seed yields of up to 500% have recently been identified (Uzun *et al.*, 2004). This observation is an indication that there is a bright future for hybrid sesame. In addition, the mutation breeding program of IAEA for sesame has also generated fruitful results with the development of higher yielding lines (www.JointFAO-IAEA-mutation.htm; Das *et al.*, 2003; Jain, 2005). Some advanced mutant lines were evaluated in regional and national yield trials, and the mutant-derived variety “Pungsankkae” was officially released in the Republic of Korea by crossing a local variety with the determinate mutant “dr-45” from Israel.

1.4.6 Breeding for high oil content and altered fatty acid composition

Sesame is an important source of edible oil whose demand is increasing due to the high quality of its oil. However, oil content is one of the most variable characteristics in sesame. The seed contains 34–63% oil (Yermanos *et al.*, 1972; Ram *et al.*, 1990; Ashri, 1998; Baydar *et al.*, 1999). Recently, Were *et al.* (2006a) studied the oil content of East African sesame accessions and reported a variation of between 28.7% and 51%. The wide variation in oil content is important and indicates that improvement of this character is feasible.

Variation in fatty acid composition has also been reported. For example, variation in oleic acid ranges from 32.7% to 58.2% (Yermanos *et al.*, 1972) and that of linoleic acid from 27.3% to 59.0% (Yermanos *et al.*, 1972). According to Were *et al.* (2006a) variation in oleic acid content of East African sesame ranges from 31.6% to 42%, while in linoleic acid is 42.9–54.0%. The improvement in oil composition has been achieved through conventional breeding, mainly selection of single plants or mass selection (Weiss, 1983; Pathirana, 1995). Owing to great genetic variation observed in oil content and fatty acid composition, conventional breeding made great strides in producing sesame varieties high in oil content.

1.5 Limitations of Conventional Breeding and Rationale for Transgenic Breeding

Conventional breeding has been successfully used in the past to produce many sesame cultivars. It has been used to produce shattering resistant, drought tolerant, high yielding, disease, and pest resistant cultivars/varieties (Ashri, 1998; Langham and Wiemer, 2002). However, the process of producing cultivars is sometimes slow owing to linkage drag or pleiotropic gene effects (Langham and Wiemer, 2002). For example, the breeding for shattering resistant cultivars took a long time owing to association of the desirable genes with undesirable ones.

Secondly, conventional breeding depends on the genetic relatedness between species and cultivars to allow gene transfer. Interspecific hybridization set an upper limit for gene transfer among species,

which is not the case with modern breeding tools.

Conventional breeding depends largely on the natural genetic variation and hybridization, on induced mutation to create new sources of genetic variation. Modern techniques, such as tissue culture and genetic transformation with transgenes, have more scope and could result in a faster rate of progress for sesame improvement. In addition, adopting transgenic breeding and transforming sesame with novel genes could allow for varieties to be developed that produce specialty oil. There are numerous examples from other crops where transformation with desired genes have radically changed the oil composition and in a much faster fashion than conventional breeding (Drexler *et al.*, 2003).

Owing to these limitations of conventional breeding in sesame, new approaches of molecular biology and cell culture are now increasingly being considered for sesame improvement.

2. DEVELOPMENT OF TRANSGENIC SESAME

A number of traits in sesame, such as low grain yield, sensitivity to certain environmental stresses, and insufficient diversity in oil composition, necessitate genetic improvement. Some of the desirable traits, for example, disease and pest resistance, are present in wild relatives but cannot be introgressed into the crop because of interspecific hybridization barriers. Establishment of an efficient method of gene transfer, which circumvents taxonomic barriers, would speed up the development of new varieties facilitating the use of both conventional breeding and biotechnology.

2.1 Methods Employed

A variety of techniques for cell, tissue, and organ culture including embryo rescue, micropropagation, and regeneration that would be useful in sesame improvement, have been explored (Ashri, 1998). Although much effort is put into developing tissue culture systems for the crop, it has proved to be very problematic to regenerate. Regeneration

through somatic embryogenesis has been achieved from zygotic embryos (Ram *et al.*, 1990) and seedling-derived callus (Mary and Jayabalan, 1997; Xu *et al.*, 1997) but with low efficiency in callus cultures. There are various reports on adventitious shoot regeneration through a callus phase from hypocotyl and cotyledon explants (George *et al.*, 1987; Rao and Vaidyanath, 1997; Taşkin and Turgut, 1997; Kim, 2001), with frequencies ranging between 4.5% and 25.8%. In some cases, shoot formation was not achieved (Batra *et al.*, 1991; Ganesh *et al.*, 1993). A much improved regeneration protocol from seedling cotyledon explants was recently reported (Were *et al.*, 2006b). This study showed the importance of a combined usage of the growth regulators thidiazuron (TDZ) and indole-3-acetic acid (IAA). The protocol gave a regeneration frequency of 63% and 4.4 shoots per regenerating explants.

The availability of an efficient regeneration protocol is a key requirement for developing a transformation method for any given plant species. The prevailing problem of low generation potential portrays one of the major obstacles to the application of genetic transformation to this crop. So far, the use of genetic engineering for the improvement of sesame has been limited by the lack of a transformation system. Taşkin *et al.* (1999) have demonstrated that sesame is susceptible to transformation by *Agrobacterium tumefaciens* but failed to regenerate transgenic plants from callus. Transgenic sesame (*Sesamum schinzianum* ASCH.) was produced via *Agrobacterium*-mediated transfection of a carrot calmodulin gene, *cam-4*, which was specifically expressed upon the contact of carrot cells with oligogalacturonide elicitor (Mitsuma *et al.*, 2004). *A. tumefaciens* 4404 was transformed with the constructed vector, and the crown gall tissues formed in the sesame seedlings were transferred onto appropriate media to obtain redifferentiated plants. Real-time polymerase chain reaction (RT-PCR) followed by Southern blot analysis revealed that *cam-4* gene was appreciably expressed in the transgenic plants. Transformation by *Agrobacterium rhizogenes* has been used for the production of novel compounds in sesame roots (Jin *et al.*, 2005). The antimicrobial compound, 2-isopropenylnaphthazarin-2,3-epoxide, was isolated from hairy roots of *S. indicum* by Ogaswara *et al.* (1993) established by transformation with

A. rhizogenes ATCC 15834. The content of the compound in the roots was over 50 times than that found in the mother plants. Furthermore, two new anthraquinones, 2(4-methyl-1,3-pentadienyl) anthraquinone and 2(4-methyl-3-pentenyl) anthraquinone, were also produced. However, to-date there is no report on regeneration of transgenic plants from transformed sesame roots.

Various approaches to floral transformation have been applied on sesame. The pollen tube pathway of transformation which had been reported to be irreproducible (Shou *et al.*, 2002), was recently used to produce transgenic disease-resistant sesame lines transformed with genes obtained from wild *Sesamum* species (Gao *et al.*, 2004). Were (2006) demonstrated transformation of sesame with reporter (enhanced green fluorescent protein, EGFP) and marker (neomycin phosphotransferase II) genes by *A. tumefaciens* using three different approaches, namely, floral dip, *Agrobacterium* drop suspension, and pollen infiltration. Overall transformation frequencies ranging between 3.4% and 50% were achieved depending on the method used. *Agrobacterium* drop suspension method involving controlled pollination of the flowers after inoculation with the bacteria carrying the genes of interest resulted in the highest number of transformants and gave similar transformation rate to that obtained with the pollen infiltration approach. However, low seed yield was observed in the case of pollen infiltration.

2.2 Donor Gene, Promoters, Selection of Transformed Tissue, and Regeneration of Whole Plant

As much work has not been done on genetic engineering of sesame, not much information is available about the source of transgenes used and the promoters. The available reports have used cauliflower mosaic virus (CaMV) 35S promoter for transformation (Taşkin *et al.*, 1999; Were, 2006).

Incorporation of antibiotic resistance genes in commercial transgenic plants has been a major area of controversy. Keeping in mind the fact that sesame oil as well as seeds are used for edible purposes, it would be worthwhile to go for the recently developed strategies in sesame

bioengineering that result in marker-free plants. Schaart *et al.* (2004) reported a system for production of marker-free transgenic plants that combines an inducible site-specific recombinase for precise elimination of undesired, introduced DNA sequences with a bifunctional selectable marker gene used for initial positive selection of transgenic tissue and subsequent negative selection for fully marker-free plants. Rommens *et al.* (2004) also described the development of a transient selection method to generate marker-free transgenic plants in which replacement of *Agrobacterium* T-DNA (transfer DNA) by a plant DNA (P-DNA) fragment was carried out, thereby achieving a native DNA transformation approach. This method has been derived from the fact that co-transfer of two different DNA molecules from *Agrobacterium* to a single plant cell nucleus is not necessarily followed by the co-integration of both. There are no reports on the activity and stability of inheritance of the gene and adverse effects on growth, yield and quality.

A variety of selection agents including antibiotics and herbicides may be used to screen for transformed tissues and whole plants. Different concentrations of kanamycin, hygromycin and phosphinothricin have been tested by B. A. Were and co-workers to determine the minimum levels required for *in vitro* selection of transformed callus and seedlings. On the basis of their findings the following concentrations may be applied:

	Callus	Seedlings
Kanamycin (mg l ⁻¹)	50.0	75.0
Hygromycin (mg l ⁻¹)	25.0	10.0
Phosphinothricin (mg l ⁻¹)	0.5	5.0

It is worth noting that sesame seedlings confirmed to be transformed with neomycin phosphotransferase II gene, which confers resistance to kanamycin, failed to develop lateral roots upon selection on kanamycin and could hardly get established in the soil. Hygromycin and phosphinothricin appeared to be more efficient than kanamycin but have not been tested on genetically transformed sesame.

For greenhouse selection for herbicide resistance using Basta, a 0.5% (w/v) solution was found to be the minimal concentration that completely kills

wild type sesame seedlings when sprayed with the herbicide two weeks after germination (B. A. Were and co-workers, unpublished results)

2.3 Specific Regulatory Measures Adopted

Since no genetically transformed sesame has been released commercially, there is no information available about any specific regulatory measure for sesame.

3. FUTURE ROAD MAP

For a crop to continue to develop and grow in importance, it is of great importance that new and improved varieties can be provided to the market regularly. This is also true for sesame and that the new varieties can meet the different kind of demands from the growers to the consumers of sesame products. Optimized transformation protocols for sesame, therefore, are important tools as they will allow for the use of genetic engineering to introduce new and improved traits in sesame lines. Such optimized protocols for routine transformation of sesame are not available at this stage. However, based on the results that already have been achieved in the area (see Section 2) there are reasons to believe that a breakthrough in this aspect is not far away. It is therefore important to consider the traits that can be improved in sesame using transgenic methods and what risks and concerns should be envisaged. Much can be learned hopefully from the experiences of the transgenic crops already developed.

In the following sections, a number of breeding objectives and expected products, therefore, have been suggested as potential targets in sesame and for which genetic engineering will be of importance. However, there are possibly many other objectives, for which the same techniques may facilitate improvements, when and if transformation protocols are available for sesame. Therefore, the suggested list of targets to be improved in sesame should not be considered complete.

3.1 Expected Products

In Section 1.4.1, a number of breeding objectives for sesame have been listed. Of those, improved agronomic characteristics, such as resistance to diseases and pests as well as shattering resistance and determinate growth, are important targets for which genetic engineering can facilitate improvements. Another area of significance is improvement of the nutritional qualities of the seed products, such as diversified oil composition, decreased allergenicity or the use of sesame lignans as dietary supplements.

3.1.1 Improved disease resistance

As discussed before, sesame crop bears heavy losses due to various diseases caused by a number of bacterial and fungal pests. Fungal diseases include charcoal rot, *Fusarium* rot and *Alternaria* leaf spot. Bacterial diseases include bacterial blight and seedling blight. Transgenic approach can be used to incorporate resistance in sesame against these diseases.

More recently, transgenic plants have been produced that are resistant to a wide variety of bacterial diseases. These forms of resistance follow a number of strategies, including the use of genes for bacterial toxin tolerance, antimicrobial peptides, and other defense related proteins that tend to act as bactericidal compounds (Tripathi *et al.*, 2004). Li *et al.* (2001) have reported disease resistance, to both a fungal and a bacterial pathogen, conferred by expression of Myp30, an analog of magainin, an antimicrobial peptide, in transgenic tobacco (*Nicotiana tabacum* var. Petit Havana). Another analog MSI-99, when expressed in tobacco via chloroplast transformation conferred both *in vitro* and *in planta* resistance to plant pathogenic bacteria and fungi (De Gray *et al.*, 2001). Similarly, cecropins (antibacterial lytic peptides) are considered as potential candidates to protect plants against bacterial pathogens. It has been used to confer resistance against many bacterial pathogens using transgenic approach in tobacco (Huang *et al.*, 1997), potato (Arce *et al.*, 1999), apple (Norelli *et al.*, 1998), and poplar (Mentag *et al.*, 2003). Transgenic apple expressing attacin, another

antibacterial protein, targeted to the intercellular space, where *Erwinia amylovora* multiplies before infection, has significantly reduced fire blight, even in apple plants with low attacin production levels (Ko *et al.*, 2000). Plants have their own networks of defense against plant pathogens that include a vast array of proteins and other organic molecules produced prior to infection or during pathogen attack. Recombinant-DNA technology allows the enhancement of inherent plant responses against a pathogen by either using single dominant resistance genes not normally present in the susceptible plant (Keen, 1999) or by choosing plant genes that intensify or trigger the expressions of existing defense mechanisms (Bent and Yu, 1999; Rommens and Kishmore, 2000). The *bs2* resistance gene of pepper specifically recognizes and confers resistance to strains of *Xanthomonas campestris* pv. *vesicatoria* (*Xcv*) that contain the corresponding bacterial avirulence gene, *avrBs2* (Tai *et al.*, 1999). Transgenic tomato plants expressing the pepper *bs2* gene suppress the growth of *Xcv*.

The production of enzymes capable of degrading cell walls of invading phytopathogenic fungi is an important component of the defense response of plants. The timing of this natural host defense mechanism has been modified to produce fungus-resistant plants. Transgenic tobacco seedlings constitutively expressing a bean chitinase gene under control of the CaMV 35S promoter showed an increased ability to survive in soil infested with the fungal pathogen *Rhizoctonia solani* and delayed development of disease symptoms (Roby *et al.*, 1990). A similar approach can work for engineering resistance to bacterial and fungal pathogens in sesame.

3.1.2 Improved pest resistance

Sesame has a serious problem of pest infestation. Resistance to these pests belonging to Lepidoptera, Diptera, and Coleoptera can be engineered into this crop through genetic engineering (Estruch *et al.*, 1997; Gatehouse and Gatehouse, 1998; Babu *et al.*, 2003). *Bacillus thuringiensis* (*Bt*) produces one or more insecticidal crystal proteins (ICPs or Cry proteins) during sporulation (Höfte and Whiteley, 1989). The Cry family of *Bt* insecticidal proteins is widely utilized in classic and transgenic approaches to control insect pests.

Also, enzyme inhibitors, proteinase inhibitors, α -amylase inhibitors, lectins, and enzymes have been applied or tried (Gatehouse *et al.*, 1997; Lee *et al.*, 1999; Haq *et al.*, 2004; Sharma *et al.*, 2004; Vila *et al.*, 2005). Similar strategies can be used to transfer these traits into sesame.

3.1.3 Improved seed retention

The shattering is considered as a domestication trait that has been modified years ago in most major crops. The progress from sequencing of the *Arabidopsis* genome, extensive molecular and genetic studies, and the detailed investigations of the seed pod and the mechanism behind seed dispersal have provided new insight into the events leading to pod shattering and release of seeds. Today, a number of genes involved in the transcriptional network controlling seed dispersal in *Arabidopsis* have been identified and characterized (Lewis *et al.*, 2006). The accumulated knowledge is now available and there are some examples in how this has been used in a transgenic approach of improving seed retention in various crops. Expressing the *Arabidopsis* *FRUITFULL* gene in *Brassica juncea* resulted in shattering resistant pods (Ostergaard *et al.*, 2006). In another example, expression in rapeseed of a MADS box gene *MADSB* from mustard, resulted in siliques with a closed valve-replum boundary that prevented seed release (Chandler *et al.*, 2005). Major loci controlling shattering in American wild rice (*Zizania palustris* var. *interior* L.) have been discovered and molecular markers that will allow for more efficient breeding for shattering resistant varieties are being developed in (Kennard *et al.*, 2002). In addition, individual genes for shattering in rice have been mapped to a specific cluster on chromosome 7 from where they now can be isolated (Ji *et al.*, 2006). The authors propose that this cluster can be referred to as a domestication block since several genes involved in crop domestication are closely linked to this region of chromosome 7. A strategy for developing shattering resistance in oilseed rape that were set up by Ulvskov (1996) could perhaps serve as a model approach for how to improve seed retention in sesame. Suppressing the expression of the gene encoding for polygalacturonase responsible for degradation of pectin in the middle lamella in the pod dehiscence zone would lead to

Pods lacking the possibility to open up. By fine tuning the suppression of the genes could lead to sesame capsules that would not shatter prior to harvest but at harvest.

3.1.4 Determinate flowering

The indeterminate growth habit of sesame causes non-uniform ripening of the capsules. As a solution to this problem, breeding for a determinate growth habit in sesame has become an active area of research after the discovery of dt-45, which was the first determinate mutant in sesame (Ashri, 1981). The molecular characterization of this mutant can throw some light on the genes in sesame involved in the determinate flowering trait. Thereafter, this trait can be bred into any sesame germplasm using the transgenic approach or marker-assisted selection.

Further exploration of this area could be aided by the recent advances in the understanding of the developmental transition in plants, from vegetative to reproductive growth (Blazquez *et al.*, 2006). When a plant “decides” to flower, this is influenced by different factors such like day length, light regime, and temperature. In *Arabidopsis* this is known to be regulated through four different pathways that act on a key repressor, the *FLOWERING LOCUS C (FLC)* (Finnegan *et al.*, 2005; He and Amasino, 2005). *FLC* controls several downstream genes that in turn activate genes responsible for the production of flower primordia. The growing understanding of how the complex regulation of the *FLC* is coordinated holds great promises for using genetic engineering and fine tuning the initiation of flowering in sesame. Recently, three genes from Chinese cabbage (*Brassica rapa* L. ssp. *pekinensis*) and homologs of the *Arabidopsis FLC*, were expressed in *Arabidopsis* and Chinese cabbage (Kim *et al.*, 2006a). The flowering time was significantly delayed in *Arabidopsis* as well as in the transgenic Chinese cabbage, which clearly shows the potential in modifying the onset of flowering. Other genes have been identified that potentially could be used to control the termination of flowering, for example, *TERMINAL FLOWER1* and *2 (TFL1, TFL2)* (Larsson *et al.*, 1998; Foucher *et al.*, 2003; Kotake *et al.*, 2003). Out of the accumulated knowledge about how the transition

from juvenile to adult vegetative development or from vegetative to reproductive growth is controlled, a model has emerged that involves small interfering RNA (siRNA) that works in *trans* (Baurle and Dean, 2006). If this holds true it could open up for using transgenic RNA silencing techniques to develop sesame varieties with determinate flowering. Interestingly, the mobile trigger for flowering known since long as “florigen” (Colasanti and Sundaresan, 2000), was recently identified to be a protein (*Flowering locus T* or *FT*) that is produced in the leaves and moves in the phloem to the shoot apex where it induces flowering (Abe *et al.*, 2005; Wigge *et al.*, 2005; Corbesier *et al.*, 2007; Tamaki *et al.*, 2007).

3.1.5 Herbicide tolerance

Early season weeds significantly reduce sesame yields. After planting, sesame is not highly competitive with weeds (Sharma, 1985). Annual weeds create a shade canopy and intercept sunlight above the crop. Even moderate infestation of annual weeds reduces sesame seed yields up to 135% (Grichar *et al.*, 2001a). As much as 10 000 acres of sesame have been discarded in some years because of weed infestations. Sesame typically grows 0.9–1.8 m tall, which creates a shade canopy and, due to its height advantage, suppresses late-season weeds (Smith *et al.*, 2000). Tillage, manual weeding or herbicide application is practised to control weeds in sesame. Recently several soil-applied herbicides as well as various postemergence herbicides were tested for sesame tolerance (Grichar *et al.*, 2001a, b). Due to yield reductions from damage inflicted by all broad leaf herbicides, they recommended soil-applied herbicides for broad leaf weed control. Introducing herbicide tolerance through the transgenic approach could be an efficient way of controlling weeds in sesame cultivation and subsequently increasing the seed yields. Herbicide tolerance would be specifically important in the early phase of establishing the sesame plants and particularly for controlling broad leaf weeds.

3.1.6 Diversified oil composition

Sesame is known to be very rich in genetic variability. However, while there is quite a bit

of variability in the oil content among cultivars ranging from 34% to 60% (Ashri, 1998; Were *et al.*, 2006a), most of the current varieties have a low diversity in the oil composition. The general oil composition is 9–11% palmitic, 5–7% stearic, 36–45% oleic, and 38–52% linoleic fatty acid (Kamal-Eldin, 1993; Namiki, 1995; Were *et al.*, 2006a). Using genetic engineering to create a more diverse fatty acid composition in the oil should make sesame more attractive in the competition with other oilseed crops, such as soybean and groundnuts. There are numerous examples today where radical changes have been introduced in the oil composition of many oil crops (for a review, see Thelen and Ohlrogge, 2002). Introduction of new cultivars with a wide diversity in the oil composition will not only improve sesame oil in its present areas of usage but also allow it to diversify out into new areas of usage, thereby increasing its market value. For example, a drawback that may hamper an increased usage of sesame oil is its low level of nutritionally important omega (ω)3 fatty acids. Sesame has high levels of ω 6 fatty acid (linoleic) and insignificant content of ω 3 fatty acids (1–2% α -linolenic). An unbalanced ω 6/ ω 3 fatty acid ratio in the western diet has been recognized as a factor behind many recent health problems like heart disease, arthritis, and inflammatory and autoimmune diseases (Simopoulos, 1999). The relative proportions of ω 6 to ω 3 fatty acids in food has been suggested to be a more important health factor than high intake of the long chain ω 3 fatty acids alone (Horrobin *et al.*, 2002). Therefore, raising the levels of ω 3 fatty acids in sesame will help to increase the usefulness of sesame oil in aiding in the battle of this dietary problem.

Changing the fat quality in a crop with respect to the ω 6/ ω 3 balance has been recently demonstrated. A total content of upto 40% of ω 3 fatty acids was reported from rapeseed transformed with Δ 15 and Δ 6 desaturase genes (Ursin, 2003). The total content of ω 3 fatty acids was 50% and the ratio of ω 6/ ω 3 was 1:2. Expression of a Δ 6 desaturase in soybean resulted in a production of upto 35% of total ω 3 fatty acids (Sato *et al.*, 2003). The aim of their research was to create oil crops as a source from which unique fatty acids can be extracted in masses.

Another example of expanding the area of usage for sesame oil would be to target the enzyme responsible for high levels of linoleic fatty acids,

i.e., the Δ 12 desaturase. The coding gene for this enzyme in sesame was recently identified and characterized (Jin *et al.*, 2001). Down-regulating the expression of the sesame Δ 12 desaturase gene using RNAi interference would constitute an efficient approach to decrease the activity of the same enzyme. The RNAi-mediated silencing are facilitated by publicly available vectors optimized for generating the hairpin RNA molecules that triggers gene silencing (Miki and Shimamoto, 2004; Helliwell and Waterhouse, 2005). The oil produced in the resulting transgenic sesame will be highly enriched in oleic acid. Such oil constitutes an excellent choice as cooking oil. A similar approach was recently successfully tried in cotton (Liu *et al.*, 2002). Silencing of the Δ 12 desaturase by post-transcriptional gene silencing raised the levels of oleic fatty acids from 13% to 78%. The resulting high oleic cotton oil has excellent properties as cooking oil.

3.1.7 Decreased allergenicity

It was recently reported that sesame had quickly risen to become one of the top food allergens (Gangur *et al.*, 2005). Food products containing sesame in any form are, therefore, now required to be labelled as potential allergenic in Europe and Canada. About 65% of all plant food allergens are caused by the presence of proteins that belong to only four different protein families (Jenkins *et al.*, 2005). A prominent sesame allergen, a 14 kDa 2S albumin precursor, belongs to one of the four families, i.e., the prolamins (Wolff *et al.*, 2003). Jenkins *et al.* (2005) pointed out that conserved structures or epitopes, among the potent proteins are important for their allergenic properties. In the example of the 14 kDa 2S albumin precursor it was shown that the allergic reaction coincided with a distinct structure of the proteins chain corresponding to residues 24–94 (Wolff *et al.*, 2003). Recently candidates for a new class of major allergens in sesame were found to be oleosins (Leduc *et al.*, 2006). The authors suggested that a reason for the previous lack of detecting oleosin as potent allergens by SPT (skin prick test), could be that their epitopes may be masked by the proteins tertiary structure (Leduc *et al.*, 2006).

An attractive strategy to reduce the allergenicity in a food crop like sesame could be to remove

or alter only the epitopes responsible. Shewry *et al.* (2001) suggested using protein engineering to design homologous and non-allergenic proteins with similar functions to the original ones and express these in the plant of choice. The allergenic epitope in the major apple allergen, *Mal d 1*, was removed by changing a serine to a proline in the protein structure suggesting the success in the above approach (Son *et al.*, 1999).

3.1.8 Antioxidant lignans as a dietary supplement

It was reported that sesame seeds contain lignans comprising 0.5–1.0% of seed dry weight. Sesame lignans are known to have antioxidant activities including elevating plasma γ -tocopherol, enhancing vitamin E bioactivity, and inhibiting proliferation of human cancer cells (Coonev *et al.*, 2001; Miyahara *et al.*, 2001). Although sesame lignans have long been of interest as a dietary supplement, most of the enzymes involved in the biosynthetic pathways leading to sesame lignans have not been identified owing to the difficulty of protein purification. Based on radio- and stable-isotopically labeled precursor administration experiments in sesame seeds, it was proposed that tyrosine or phenylalanine is first converted into coniferyl alcohol by the phenylpropanoid pathway. Two coniferyl alcohols are subsequently coupled to pinoresinol, and then pinoresinol is converted into “oxygen-inserted” lignans, sesamol, or sesamin via piperitol containing a single methylenedioxy bridge (Jiao *et al.*, 1998; Kato *et al.*, 1998). As an initial approach to identify genes involved in the biosynthesis of antioxidant lignans, 3328 expressed sequence tags (ESTs) were obtained from a complementary DNA (cDNA) library of 5–25-day-old immature seeds. Preliminary identification of EST candidates corresponding to each enzymatic reaction in the biosynthetic pathway of sesame lignans was carried out (Suh *et al.*, 2003).

In the phenylpropanoid pathway for the formation of coniferyl alcohol from phenylalanine or tyrosine, caffeic acid *O*-methyltransferase (COMT), which was abundant in sesame developing seed ESTs, was proposed as a catalyst for *O*-methylation leading to coniferyl alcohol. Three ESTs encoding dirigent protein were detected

in developing sesame seed ESTs, suggesting that a dirigent protein might be involved in the reaction of bimolecular phenoxy radicals for the formation of pinoresinol from coniferyl alcohol in developing sesame seeds. According to the previous observation, that a methylenedioxy bridge formation for the synthesis of piperitol was catalysed via an O_2 /NADPH-requiring cytochrome P450-dependent enzyme (Jiao *et al.*, 1998), seven sesame EST candidates possibly involved in methylenedioxy bridge formation and oxygen insertion were identified (Suh *et al.*, 2003). Although only a few genes involved in the biosynthesis of sesame lignans are available to date, identification of functional activity of the genes and elucidation of the pathways involved in sesame lignan production will provide useful information in industrial applications of sesame lignans as a dietary supplement.

3.2 Addressing Risks and Concerns

Concerns about genetically modified (GM) crops include transgene flow to compatible wild species and unintended ecological consequences of potential transgene introgression (Snow, 2002; Ellstrand, 2003). However, there has been little empirical documentation of establishment and distribution of transgenic plants in wild populations. The first global evidence of transgene escape into natural weedy populations was only recently reported for herbicide (glyphosate) resistant *Brassica* (Warwick *et al.*, 2003, 2004). Reichman *et al.* (2006) have reported glyphosate-resistant creeping bentgrass (*Agrostis stolonifera* L.) plants expressing *CP4 EPSPS* transgenes outside of cultivation area in central Oregon in US.

Sesame is usually considered to be a self-pollinated crop (Kinman and Martin, 1954) although the amount of cross-pollination that occurs is considerable. Honeybees are the primary pollinators in sesame (Langman, 1944). However, sesame has a large diversity in the African and Asian continents with many wild species. Also, other *Pedaliaceae* members, such as *Ceratotheca sesamoides*, share close proximity to *Sesamum*. This plant has edible uses; its leaves are used as valuable leaf vegetables play in daily life in African countries, particularly during times of shortage and famine. All these factors pose a potent risk in

development of transgenic sesame in the countries where wild sesame also exists. Also, sesame being a source of edible oil and seeds, the food safety and biosafety concerns would be major. Efficient management strategies would have to be in place for management of *Bt* or herbicide tolerant sesame, whenever developed in future.

3.3 Expected Technologies

3.3.1 Improved transformation efficiency

Sesame can boast of very few reports on efficient and reproducible system of regeneration from somatic tissues. The low potential for shoot morphogenesis of this species has affected the success achieved in optimization of a genetic transformation method. Establishment of an efficacious protocol for *Agrobacterium*-mediated genetic transformation is the first step in the development of transgenic sesame resistant to any disease or shattering.

3.3.2 Identification of specific promoters

The metabolic engineering of complex traits often requires more than one promoter for the introduction of multiple genes. In the examples mentioned above with diversified oil composition or decreased allergenicity, seed-specific promoters are required for developing transgenic sesame plants. At present, the napin storage protein promoter from *Brassica napus* and the rice glutelin promoter are utilized extensively for the expression of introduced genes in dicotyledonous and monocotyledonous transgenic seeds, respectively (Poirier *et al.*, 1999; Rezzonico *et al.*, 2004; Paine *et al.*, 2005). Recently the promoter of the seed-specific microsomal $\Delta 12$ desaturase gene (*SeFAD2*), which functions by inserting a double bond between carbons 12 and 13 of oleic acid at both the *sn*-1 and *sn*-2 positions of phosphatidylcholine, was isolated from *S. indicum*. When the β -glucuronidase (GUS) reporter gene under the sesame seed-specific *SeFAD2* promoter was introduced into *Arabidopsis* plants, GUS expression was restricted to the mid- and late-developmental phases of the developing seeds,

which is consistent with the timing of storage lipid accumulation. Deletion analysis of the *SeFAD2* promoter revealed that –660 to –180 promoter region functions as a negative *cis*-element in the seed-specific expression of the *SeFAD2* gene. And the –179 to –53 region of the *SeFAD2* promoter was found to harbour positive *cis*-elements, which are associated with the quantitative regulation of *SeFAD2* gene expression during seed development. Eight potential *cis*-elements—the (CA)₂ element, E-box, CCAAT box, G-box, ABRE motif, G-box-like element, RY repeat element, and P-box—all of which have been implicated in the regulation of gene expression in developing seeds, were represented in the –179 to –53 region of the *SeFAD2* promoter (Kim *et al.*, 2006b). The results suggested that the *SeFAD2* promoter might be useful for the modification of the seed phenotypes of transgenic plants.

Promoters controlling gene expression in a tissue-dependent manner and according to the developmental stage of the plant are desired over constitutive promoters. The transgenes driven by these type of promoters will only be expressed in tissues where the transgene product is desired, leaving the rest of the tissues in the plant unmodified by transgene expression. In sesame, seed-specific promoters will be useful in fatty acid profile engineering. Root-specific promoters can play an important role in developing bioengineered sesame resistant to wilt. Dehiscence zone-specific promoters will be extremely valuable in developing shattering-resistant transgenic sesame.

3.4 Intellectual Property Right (IPR), Public Perceptions, Industrial Perspectives, Political and Economic Consequences

Till date, there are no IPRs for any genetically engineered sesame variety or process. However, certain shattering-resistant varieties which have been developed by Sesaco in the United States are protected by patents (US Patent No. 6 100 452). Sesame is used in traditional foodstuffs of many Asian and African countries. The concerns of these native people also need to be kept in mind while developing biotechnological approaches in sesame, one of the ancient oilcrops of the world.

1. INTRODUCTION

Health is one of the major concerns in today's fast-paced life. With the increase in awareness, more and more people are switching toward healthy food habits. A lot of attention is being paid to dietary habits including the oil in which food is cooked. Oils which are unsaturated, high in nutrition, have good shelf life, and do not turn rancid are preferred. Among the oil crops, few qualify these criteria and safflower (*Carthamus tinctorius* L.) happens to be one of these (Dajue and Mündel, 1996; Weiss, 2000). The current review focuses on the biology, breeding, and biotechnological progress in transgenic research of the genus *Carthamus*.

1.1 History, Origin, and Diversification

Safflower is believed to have originated in Mediterranean region (Garnatje *et al.*, 2006). The domestication of the plant has been indicated in 2000 BC in Egypt, for the orange dye obtained from the florets. However, later it was cultivated for oil. Revenue papyrus of Ptolemy II, 259–258 BC, is also indicative of safflower being cultivated as an oil crop. According to Pliny (1st century AD), in Egypt, safflower was used as a milder substitute for castor oil. In 1000 AD, Mesua, an inhabitant of Baghdad, in his work on contemporary Arab

and Greek medicine, named the plant as *cnicus*. He noted the existence of both wild and cultivated varieties. Safflower was probably introduced to China during AD 200–300 as a source of dye and cooking oil. Western expansion of the Arabs in 5th and 6th centuries promoted spread of safflower cultivation along Maghreb and into Europe via the Iberian Peninsula. From Irano-Afghanistan area, it was introduced into southern Russia. From China it was introduced to Japan. Safflower became a major crop of the United States after World War II. For a detailed account on these aspects, readers are referred to Weiss (2000).

1.2 Habit, Habitat, Taxonomy, Cytogenetics, and Genetic Resources

Safflower is commonly known as “kusum” in India and Pakistan, “honghua” in China, and as “false saffron” in various other countries. It is a branched, thistlelike, medium sized (30–150 cm), herbaceous annual, with numerous spines on leaves and bracts (Dajue and Mündel, 1996; Weiss, 2000). It has a tap root system, which penetrates deep into the soil. The life cycle of plant constitutes a slow-growing rosette stage followed by an active vertical growth-preceding flowering. The elongation starts with the increase in day length and temperature. During this period, plant elongates quickly, produces number of branches,

and subsequently each branch is terminated by an inflorescence, which is a capitulum. Safflower is a self-pollinated crop. However, certain degree of outcrossing has also been reported (Claassen, 1950). The main pollinators of safflower are bees (*Apis mellifera*). After 4–5 weeks of flowering, each capitulum produces 15–30 or more achenes from which oil is extracted (Dajue and Mündel, 1996; Weiss, 2000).

Safflower is a crop of warm temperate region. It can be grown as an autumn sown crop in the northern hemisphere and under irrigation in the dry tropical regions (Weiss, 2000). Traditionally, it is a crop grown in the Mediterranean to Pacific Ocean belt at latitudes between 20°S and 40°N (Dajue and Mündel, 1996; Weiss, 2000). Although safflower is drought tolerant due to its deep penetrating tap root system, it grows best in well drained, deep, fertile, and sandy loam soils. Safflower is used as a support crop in drought prone areas and can help prevent dry land salinity. However, it cannot withstand waterlogging (Dajue and Mündel, 1996).

Carthamus, belonging to the family Asteraceae is composed of 15 species. It is distributed from Spain, North Africa, West Asia to India (Vilatersana *et al.*, 2005). Among its species, only *C. tinctorius* exists under cultivation. *C. tinctorius* is diploid with 12 pairs of chromosomes ($2n = 24$). It is understood to have originated from a cross between self-compatible as well as self-

incompatible *Carthamus oxycanthus* ($2n = 24$) and self-incompatible *Carthamus persicus* ($2n = 24$; Ashri and Knowles, 1960), which in turn have originated from *Carthamus palaestinus* ($2n = 24$), a self-compatible species (Figure 1; Imrie and Knowles, 1970; Khidir and Knowles, 1970). All the four species have been given genome formula BB and are reported to intercross in all combinations and produce fertile hybrids. In addition, there are other safflower species such as *Carthamus arborescens*, *Carthamus rhiphaeus*, and *Carthamus nitidus*, which have $2n = 24$ but do not qualify for BB genome (Ashri and Knowles, 1960; López-González, 1990). Some *Carthamus* species produce purple, blue, and pink flowers. These are *C. boissieri*, *C. dentatus* having genome formula A_1A_1 , *C. glaucus* and its subspecies having genome formula AA or AA/A_3A_3 , *C. leucocaulos* with genome formula A_2A_2 , and *C. tenuis* (Dajue and Mündel, 1996). A few species of *Carthamus* have 11, 22, and 32 pairs of chromosomes. These are *C. divaricatus* ($2n = 22$), *C. lanatus* ($2n = 44$) having genome formula $A_1A_1B_1B_1$, *C. creticus* having genome formula $A_1A_1B_1B_1A_2A_2$, and *C. turkestanicus* ($2n = 64$) having genome formula $A_1A_1B_1B_1AA$, whereas *C. glaucus* has $2n = 20$. Knowles (1958) divided the species of *Carthamus* into four sections based on the chromosome number with those having $n = 12$ in section I, $n = 10$ in section II, $n = 22$ in section III representing only *C. lanatus*, and $n = 32$ in section IV containing

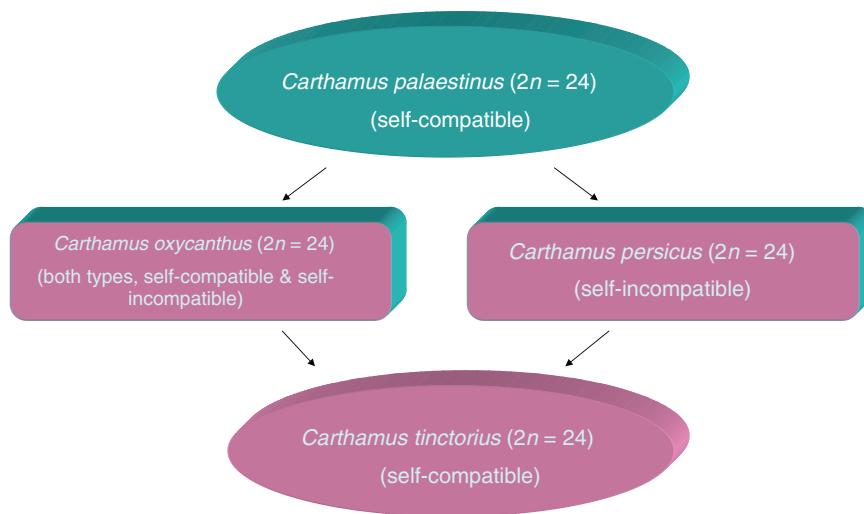

Figure 1 Proposed origin of *Carthamus tinctorius* [Reproduced from Dajue and Mündel (1996)]

two species *C. creticus* and *C. turkestanicus*. Estilai (1977) added one more section V to this to represent *C. divaricatus*, the only species having $n = 11$. On the contrary, on the basis of morphological characters, Hanelt (1963) established five sections under the genus *Carthamus*. These sections were *Thamnacanthus* ($n = 12$), *Carthamus* ($n = 12$), *Odontagnathius* ($n = 10$), *Lepidopappus* ($n = 10$ and 12), and last section *Atractylis* ($n = 11, 22$, and 32). The species under *Thamnacanthus* were put in a separate genus *Phonus* (López-González, 1990; Vilatersana *et al.*, 2000). As the classification of the genus *Carthamus* was considered ambiguous, Vilatersana *et al.* (2005) used random amplified polymorphic DNA (RAPD) markers to resolve the taxonomic problems related to the genus *Carthamus*. Based on their study, Vilatersana *et al.* (2005) reduced the number of sections from five to two. These were *Carthamus* and *Atractylis*. The other two sections *Lepidopappus* and *Odontagnathius* were also included in the latter section. The status of *Thamnacanthus* of Hanelt (1963), species of which were already put in a different genus *Phonus*, was not changed (Vilatersana *et al.*, 2005).

The centers of origin and producing areas of safflower are rich in its genetic resources. Knowles (1969) coined the term “centers of similarity” to identify seven regions that have remarkably similar safflower types. These centers are not necessarily the centers of origin but are the regions having abundance of safflower. Ashri (1973) added three more centers of similarity to this list. Patel *et al.* (1989) confirmed the fact that factors other than geographic isolation contribute to the genetic diversity of *C. tinctorius*. About 25 179 accessions of safflower germplasm have been collected and conserved in 22 gene banks of 15 countries throughout the world (Zhang and Johnson, 1999).

1.3 Economic Importance

Carthamus is valued for both its oil and dye, carthamin. The use of carthamin as dye is since times immemorial. It was used to anoint Egyptian mummies 4000 years ago. *Carthamus* as a source of dye and oilseed has been mentioned in scriptures of different cultures. The medicinal value of safflower was also long realized as evident from *Materia Medica* (Weiss, 2000).

C. tinctorius was originally domesticated for its dye, carthamin, extracted from its petals. This was used for coloring rice, bread, pickle, cheese, sausages, etc. and for dyeing clothes and carpets (Weiss, 2000). The tubular florets are commonly used as an adulterant or cheaper substitute for saffron; hence the name bastard saffron was given to the plant. The soot from charred safflower plants was used as local eye cosmetic, kohl in Egypt. Less thorny varieties of safflower are used as vegetable or as fodder for livestock (Weiss, 2000).

Currently, safflower is grown mainly for oil and in some parts of the world for birdseed. It produces two types of oils, one rich in monounsaturated fatty acid (oleic acid, MUFA) and the other rich in polyunsaturated fatty acid (linoleic acid, PUFA). Both contain chiefly palmitic acid (16:0), stearic acid (18:0), oleic acid (18:1), linoleic acid (18:2), and linolenic acid (18:3). Depending on the genotype, the percentages of these constituents vary (Singh and Mehta, 1992; Friedt, 1994). The genetic analyses of safflower has revealed that the linoleic acid and oleic acid levels in seed oil are controlled by a single gene (Horowitz and Winter, 1957; Knowles and Mutwakil, 1963; Friedt, 1994) having three alleles *OL*, *ol*, *ol^l* (Knowles, 1965). Another gene, “*st*”, determines the level of stearic acid. The substitution of “*st st*” instead of “*St St*” in high linoleic acid (*Ol Ol*) or high oleic acid (*ol ol*) varieties, leads to an increase in the stearic acid content and a corresponding decrease in the content of linoleic acid or oleic acid or both (Ladd and Knowles, 1971).

Out of the two different varieties of safflower, the one rich in linoleic acid yield oil that is good for heart patients. The oil extracted is used as salad oil and in margarine. The oil extracted from varieties with high oleic acid is thermostable and is used for cooking purposes. The oil is also a rich source of vitamin E, tocopherol (Stobart *et al.*, 1997). Since high oleic acid oil is considered drying or semi-drying and has nonyellowing property upon drying, it is used in paints and varnishes. After the oil is extracted, seed cake is used as a cattle feed (Weiss, 2000). High content of linoleic acid in safflower oil can control arteriosclerosis, reduce serum cholesterol, and thus cure hypertension, high blood fat, coronary heart disease, and obesity. It can also control blood pressure, enhance physique, improve microcirculation, and recover nerve function (Dajue and Mündel, 1996). High

oleic sunflower and safflower seeds have also been used for the production of environment friendly, effective lubricants containing estolides. These lubricants can be used as hydraulic fluid in heavy equipment or as crankcase fluid (Durham and Wood, 2002). The crop, especially the high oleic acid varieties hold tremendous potential as a pollutant reducing diesel fuel additive as the oil is free of sulfur and biodegradable. This could help in reducing emissions, which would help in reducing acid rain, green house effect, and surface pollution (Bergman and Flynn, 2001).

Safflower petals are of high medicinal and therapeutic value. Safflower petals possess immunomodulating and blastogenic properties (Wakabayashi *et al.*, 1997). *Carthamus* petals are rich source of gamma-linolenic acid, which has high antifungal and antiviral properties (Srinivas *et al.*, 1999). It is useful in treatment of skin infections such as atopic eczema.

Carthamus ranks second in the world's total oilseed production and approximately 726 121 ha land is dedicated to safflower production (Camas and Esendal, 2006). According to an FAO estimate, in 2005, yield was approximately 776 327 metric tons. The chief safflower producers are India, the United States, and Mexico (Table 1,

<http://www.fao.org/es/ess/top/commodity.html?lang=en&item=280&year=2005>)

In India, it is cultivated along the Deccan peninsula in Maharashtra, Karnataka, Andhra Pradesh, Madhya Pradesh, Orissa, and Bihar (Patil *et al.*, 2003). Most of the produce is consumed domestically, owing to its increasing acceptance and improvement in the fatty acid profile. Thus, in coming years, more area is expected to be brought under its cultivation.

1.4 Traditional Breeding

In breeding, the genotypes that are stable in different environmental conditions are highly desirable. Thus, the prerequisite of any breeding program is evaluation of the germplasm and selection of stable genotypes. Ehdaie *et al.* (1977) from Iran evaluated 33 local and introduced genotypes of safflower at seven locations to understand the genotype X environment interaction. Although the selected local varieties did not exhibit significant genotype-environment interactions, the introduced varieties were significantly affected. Among the 12 introduced genotypes, only one exhibited stability and high yield in diverse environmental conditions. It highlighted the importance of locally adapted genotypes as starting material in breeding. Similarly, Ashri *et al.* (1975), evaluated germplasm from Indian subcontinent, Turkey, and Egypt at different locations in Utah, Israel, and Washington, for two strongly correlated characters, the length of the growing period from planting to flowering and plant height. These were strongly influenced by source countries and test locations. However, interestingly there was no significant correlation of these characters with the yield and oil content. This observation was utilized for selection of varieties, which had shorter growing period and were high yielding. Similarly, Ranga Rao and Ramachandram (1977) carried out an analysis of 215 entries from India and the United States for association of components of yield and oil. While a strong positive correlation of seeds per capitula and seed weight with yield per plant was observed, seed size and oil content exhibited a negative correlation due to hull thickness. Moreover, they did not observe any effect of plant height, days to flowering, and total crop

Table 1 Annual production of safflower in different countries^(a)

S. No.	Country	Production (t)
1	Mexico	2 12 765
2	India	2 10 000
3	United States of America	91 000
4	Australia	60 000
5	Argentina	51 000
6	Kazakhstan	40 000
7	Ethiopia	38 000
8	China	32 000
9	Kyrgyzstan	20 000
10	Uzbekistan	10 000
11	Tanzania	5 000
12	Tajikistan	3 000
13	Canada	2 000
14	Hungary	650
15	Iran	500
16	Russian Federation	200
17	Turkey	150
18	Pakistan	40
19	Spain	17
20	Palestine	5

^(a)Source: FAO (2005)

growth on yield and oil content. Patil *et al.* (1994) studied the efficiency of selection for desirable traits in F₂, F₃, and F₄ generations. Single plant selections from F₂ progenies were carried out based on number of capitula per plant, number of seeds per capitulum, test weight, and seed yield. Among various selection classes, number of capitula per plant and yield per plant were observed to be the important parameters in individual plant selection in early segregating generations. It was observed that selection based on these characters had potential of genetically improving the productivity of cultivated varieties of safflower. Likewise, Ramachandram and Goud (1981) studied the inheritance of seed yield and oil content in a diallel cross between F₁ and F₂. The combining analysis revealed the predominance of *gca* variance for plant height, total capitula, seed weight, seed number, and seed yield in F₁ and F₂ generations, and for days to flowering and oil content in F₁.

For breeding, it is important to know the existing variability and the interspecific relationship within the existing divergence. To understand the diversity, allozyme patterns of alcohol dehydrogenase, governed by two gene loci *Adh1* and *Adh2* were studied in 1553 cultivated varieties of safflower by Efron *et al.* (1973). The study helped in understanding the interspecific relationships in the genus *Carthamus* and the origin of polyploid species, namely, *C. lanatus*, *C. baeticus*, and *C. turkestanicus*.

One of the major challenges for safflower research and development is development of cytoplasmic male sterile lines to be used for production of hybrids of commercial importance. This need has emerged primarily due to lack of suitable well-functioning male sterility systems, though structural and genic male sterility systems in safflower do exist (Heaton and Knowles, 1982; Hill, 1989; Weisker, 1996). However, these cannot be utilized to a large extent at a commercial scale for want of desirable hybrids. Among all techniques, chemical male sterility is believed to be more cost effective and a practical approach. The utilization of chemicals for achieving male sterility in safflower has stemmed from series of reports where the hormonal regulation of flowering has been emphasized (Baydar and Ülgen, 1998; Baydar, 2000). It was found that gibberellic acid can induce male sterility in plants. Baydar and

Gökmen (2003) obtained reduced pollen viability from 81.6% to 6.7% in safflower after three foliar sprays with 100 ppm GA₃ after 75, 82, and 89 days.

The yield of safflower is adversely affected by a number of pathogens and pests. Breeding for disease/pest resistance has been one of the major thrust areas of research in safflower. It requires screening of large number of genotypes for selection of donor(s) possessing resistance genes, which is then bred with the cultivated varieties. Ashri (1971) screened about 2000 accessions of *C. tinctorius* and nine wild species for selecting genotypes resistant against safflower fly, *Acanthophilus helianthi*. Only two closely related species, *Carthamus flavus* and *C. palaestinus* showed fly-free accessions and, therefore, these were projected to be the potential donors for safflower fly resistance gene. One of the key barriers in breeding is incompatibility between the donor plant and the cultivated variety, which leads to no or sterile hybrids. Therefore, it is imperative to study the breeding behavior of the cultivated varieties along with closely, distantly, and unrelated wild species for proper gene tapping. Ashri (1974) studied natural hybridization of the cultivated safflower, *C. tinctorius* and unrelated wild species *C. tenuis*. It was found that the two formed sterile hybrids. However, it was supposed that continuous pollination might have produced viable seeds and introgression somewhere in the wild must have taken place. Similarly, drought hardiness and resistance to *Alternaria* leaf blight have been partly incorporated into cultivated types by crossing with the resistant accessions or species and followed by repeated backcrossing and selection (Mündel and Huang, 2003).

Certain agronomic traits such as size of capitulum and length of involucre bracts are expected to be directly related to yield. Thus, cultivars with large heads and smaller outer involucre bracts are the desired ones. Ashri *et al.* (1975) evaluated 900 lines from over 20 countries for these characters. Considerable variability within the regional pools was observed. However, the correlation of these two characters with yield was observed to be inconsistent (Ashri *et al.*, 1975). Selection of the desired trait depends largely on the selection criteria adopted. In addition to yield components, there are other factors, which indirectly affect the yield. In many

instances, it has been observed that a single trait-governing yield affects one or more other traits either positively or negatively. Thus, most of the workers use path analysis to define the best selection criteria. The number of capitula/plant, number of seeds/capitulum, weight of seed, and capitulum diameter are considered important yield components (Patil and Jadhav, 1977; Chaudhary, 1990; Prasad *et al.*, 1993; Prasad and Agrawal, 1994; Pascual-Villalobos and Alburquerque, 1996; Omid Tabrizi, 2000). Likewise, total biomass, plant height, leaf number, number of primary branches, capitula/plant and seeds/capitulum 1000-seed weight, seed weight/capitulum, distance between ground level and the first fertile branch, number of days to the beginning of branching and flowering duration have also been found to have a significant positive effect on the seed yield (Chaudhary, 1990; Bidgoli *et al.*, 2006).

1.5 Limitations of Conventional Breeding and Rationale for Transgenic Breeding

Genetic transformation is an edge-cutting technology that allows the transfer of useful genetic information, within and across the taxonomic boundaries, resulting in new and novel genotypes. The same can be assiduous and time consuming through conventional means. For instance, it takes 5–10 years of repeated back crossing and selfing to introgression of a desirable trait from a landrace or a closely related species into the recipient parent, through conventional breeding methods. Moreover, if the donor parent is evolutionarily a distant relative, it takes even longer. Furthermore, such wide crosses do not take place easily because of the pre and postfertilization barriers (Jauhar, 2001). In addition, in few instances, due to linkage drag, many undesirable genes also get incorporated along with the gene of interest. However, genetic engineering overrides all such coercions and offer precise incorporation of the desired gene. Although incorporation of a gene is a single-step process, the development of a transformed or a transgenic plant involves several distinct steps, namely, gene selection, insertion, integration, expression and demonstration, and elucidation of its inheritance (Webb and Morris, 1992).

2. DEVELOPMENT OF TRANSGENIC SAFFLOWER

2.1 Transgenes

The expression of a foreign gene in an alien genetic background is hampered because of the gene's inability to use host's regulatory sequences for transcription. Thus, for expression of a foreign gene, the plasmid construct is designed in a manner that along with the "gene insert", 5' and 3' regulatory elements, capable of transcribing the inserted gene in an alien environment, are also ligated. Since most of the foreign genes are bacterial in origin, bacterial promoters such as Nos (nopaline synthase), Mas (mannopine synthase), and Ocs (octopine synthase) are commonly used. Besides bacterial promoters, CaMV 35S promoter from cauliflower mosaic virus is also used. CaMV 35S exhibits high expression of dicot, monocot, as well as bacterial "gene inserts" in the transformed plant cells (Webb and Morris, 1992).

All the transformation studies that have been carried out in safflower used *Agrobacterium tumefaciens*. Ying *et al.* (1992) used disarmed strain LBA4404 (Hoekema *et al.*, 1983) containing a binary plasmid pBI121 (Jefferson *et al.*, 1987), which had a *GUS* reporter gene driven by CaMV 35S promoter and a neomycin phosphotransferase gene (*nptII*) under control of Nos. Orlikowska *et al.* (1995), in addition to LBA4404/pBI121, used another strain EHA105/p35SGUSInt (Cardi *et al.*, 1992; Li *et al.*, 1992). Similarly, Sankara Rao and Rohini (1999) and Rohini and Sankara Rao (2000) used the bacterial strain, LBA4404 harboring a binary vector pKIWI105, which had *uidA* reporter gene driven by CaMV 35S promoter and a neomycin phosphotransferase II (*nptII*) gene driven by the Nos promoter. The reporter gene of pKIWI105 had a modified *uidA*, which lacked the bacterial ribosome binding site and showed no expression in *Agrobacterium* but showed good activity in plant cells (Janssen and Gardner, 1989). Sujatha (2006) used a construct, pCambia1305.1 harboring β -glucouronidase (*gus*) as a reporter gene and hygromycin phosphotransferase (*hpt*) as a selectable marker.

In a novel technique, Nykiforuk *et al.* (2006) produced transgenic oilseeds producing human insulin by targeting protein to oilbodies as

oleosinfusions. *Arabidopsis thaliana* plants were transformed with a binary expression vector pSBS4405. The construct had a fusion protein, oleosin + human insulin (OB-hIN), comprising recombinant human mini-insulin with an N-terminal trypsin cleavable propeptide (Klip27-mini-insulin; Kjeldsen *et al.*, 2001) fused to the C-terminus of the *A. thaliana* 18-kDa oleosin-Klip8 polypeptide (Nykiforuk *et al.*, 2006). Using a similar approach, genetically transformed safflower, capable of synthesizing insulin in its seeds was also developed at SemBioSys Genetics, Inc. As in *Arabidopsis*, a cleavage site was included to permit purification of the target protein after extraction of the oil (US Patent 2005/0039235 A1; Moloney *et al.*, 2005).

In another report, Kneusel *et al.* (1994) identified roughly 12% of brefeldin A (BFA) esterase sequence and cloned it in pUC18. One of the seven clones was sequenced and found to express full size esterase protein of 372 amino acid residues. The BFA esterase was isolated from *Bacillus subtilis*. This enzyme can hydrolyse Brefeldin A, a phytotoxin from *Alternaria carthami*, which causes devastating leaf blight disease of safflower. This investigation has opened the avenues for development of transgenic safflower resistant to *Alternaria* blight.

2.2 Transformation Methods Employed

Gene insertion into a plant can be brought about either by direct gene transfer method or *Agrobacterium*-mediated transformation. For safflower, *Agrobacterium*-mediated transformation has mostly been used. It requires co-culture of explants with the bacterium (Ying *et al.*, 1992; Orlikowska *et al.*, 1995; Sankara Rao and Rohini, 1999; Sujatha, 2006). For instance, Sankara Rao and Rohini (1999) grew *Agrobacterium* overnight in LB medium containing (50 mg l⁻¹) kanamycin. Thereafter, the bacterial cells were pelleted and resuspended in (100 ml) Winan's AB medium. The cotyledons and pricked cotyledonary nodes were incubated for 10 min in AB medium with suspended *Agrobacterium*. The explants were taken out and blot dried on sterile blotting paper and co-cultured for 2 days on regeneration medium. Thereafter, the explants were washed with regeneration medium supplemented

with (500 µg ml⁻¹) cefotaxime and after blot drying incubated on selection/regeneration medium.

In addition, Rohini and Sankara Rao (2000) developed an *Agrobacterium*-mediated *in planta* transformation technique where the *in vitro* regeneration step was completely omitted. DNA was injected directly into the plant. This method has also been used for other crops, namely, rice (Junhi and Guhung, 1995), cauliflower (Eimert *et al.*, 1992), sunflower (Schoneberg *et al.*, 1994; Sankara Rao and Rohini, 1999), etc. Rohini and Sankara Rao (2000) used 2-day-old seedlings for *in planta* transformation. For *vir* gene expression, acetosyringone (100 mM) and extract of wounded tobacco leaves (1 gm l⁻¹) were included in the medium used for suspension of *Agrobacterium*. Out of the two, tobacco leaf extract helped in improvement of the transformation efficiency while acetosyringone did not have a significant effect. Acetosyringone has been reported to increase the receptivity of the plant material and the infection ability of *Agrobacterium* and has been shown to increase the transformation frequency in safflower (Orlikowska *et al.*, 1995). For infection, 2-day-old seedlings from which one cotyledon was removed and the exposed cotyledonary nodes were pricked were incubated in *Agrobacterium* containing medium for 10 min. This was followed by co-cultivation on MS basal medium for 24 h. Thereafter, the seedlings were washed with cefotaxime (500 µg ml⁻¹) for 1 h and planted in sterile soilrite. Sujatha (2006), in addition to *Agrobacterium*-mediated transformation, had attempted direct gene transfer through particle gun bombardment. However, better results were observed by *Agrobacterium*-mediated transformation.

A group at SemBioSys Genetics, Inc. also used *Agrobacterium*-mediated transformation of leaf and stem tissues of safflower for packing important proteins in the oil storing bodies, oleosomes (Moloney *et al.*, 2005; US Patent 2005/0039235 A1; Nykiforuk *et al.*, 2006).

2.3 Selection of Transformed Tissue

The key to success of any transformation protocol is selection of the transformed cells. Although, the tumorigenic genes present in *Agrobacterium* can

be used as selection marker, this usually entails abnormal shoots and development of crown galls, which is disruptive of normal growth of the transgenic plants. The replacement of tumorigenic gene with the single dominant gene that provides resistance to a selective agent allows selection of the transformants and at the same time does not disrupt plant regeneration. A number of chemicals, mostly antibiotics, have been used as selection agents. However, a number of factors govern their efficacy. A selection agent should be toxic to growth of normal cells. Only the transformed cells, which have selectable marker gene, should be able to grow on the selection medium. The time and dose of application are also critical for elimination of untransformed cells and selection of transformed cells. The concentration of the selection agent in the medium should not be suboptimal as there may be some background resistance to the selection agent in the untransformed cells. This would lead to selection of untransformed cells as well. Similarly, time of application is critical to limit the number of nontransformed cells which would survive through cross-protection from transformed cells (Webb and Morris, 1992). Regeneration ability of the transformed cells is also affected by the kind and dosage of the selection agent used. Selection agents, such as antibiotics, severely affect the differentiation response. In the cultivar “Centennial”, exposure of the co-cultivated explants to kanamycin or gentamicin, drastically reduced the regeneration response (Orlikowska *et al.*, 1995). However, the transformed shoots could be obtained only when kanamycin selection was done after 1 or 2 days of co-cultivation. The transformation efficiency was monitored through the activity of β -glucuronidase (GUS). Antibiotics, such as kanamycin and hygromycin are the most commonly used selection agents. The genes that impart resistance against them are *nptII* and *hptII*. Sujatha (2006) used three selection agents, namely, hygromycin ($0\text{--}100\text{ mg l}^{-1}$), kanamycin ($25\text{--}500\text{ mg l}^{-1}$), and phosphinothricin ($0\text{--}10\text{ mg l}^{-1}$) for safflower. Out of these, kanamycin even at 500 mg l^{-1} was not effective, while hygromycin proved inhibitory at the lowest concentration 1 mg l^{-1} . Ying *et al.* (1992) selected transformed shoots of safflower on medium containing 500 mg l^{-1} carbencillin and 50 mg l^{-1} kanamycin.

Since Rohini and Sankara Rao (2000) followed an *in planta* method of transformation, they did not have any selection procedure. Initially, selection on kanamycin was attempted, however, the survival percentage reduced drastically. The transformed plants were screened using polymerase chain reaction (PCR) and Southern analysis, discussed under Section 2.5.

2.4 Regeneration of the Whole Plants

The success in obtaining a transgenic plant depends essentially on (i) the competence of the cell or tissue to take up and integrate foreign DNA into its genome and (ii) the ability of the transformed tissue to regenerate into plantlets (Potrykus, 1990). Thus, a tissue for which an *in vitro* regeneration protocol has been standardized or the one having a high natural regeneration potential, such as shoot apical meristem, is used for transformation. For safflower, a number of regeneration protocols either through somatic embryogenesis (Mandal *et al.*, 1995, 2001; Mandal and Dutta Gupta, 2003) or organogenesis (George and Rao, 1982; Tejavathi and Anwar, 1984; Baker and Dyer, 1996; Nikam and Shitole, 1999; Walia *et al.*, 2005; Radhika *et al.*, 2006) have been reported. However, regeneration response in safflower is highly variable and is dependent on number of variables, namely, genotype, culture media, culture conditions, etc. Moreover, rooting of the *in vitro* regenerated shoots and field transfer too pose major limitations (Baker and Dyer, 1996; Walia *et al.*, 2005; Sujatha, 2006). Despite that, a number of transformation protocols have been developed with at least one of them reaching commercial scale.

The explants that have been used in transformation of safflower are cotyledons (Ying *et al.*, 1992; Orlikowska *et al.*, 1995), leaves (Orlikowska *et al.*, 1995), and apical meristems (Orlikowska *et al.*, 1995). The regeneration of transgenics from explant other than apical meristem is mostly via a callus phase, which is genotype dependent and gives rise to sectorial chimeras (Ying *et al.*, 1992; Orlikowska *et al.*, 1995). On the other hand, regeneration from apical shoot meristem is direct, genotype independent, and yields both homohistonts and chimeric transgenics (Orlikowska *et al.*, 1995). The time

at which the explant is exposed to the selection agent is also critical step for the conversion of a transformed cell into a transgenic plant. Orlikowska *et al.* (1995) observed regeneration only in those explants, which were transferred to selection medium after 1 or 2 day(s) of co-cultivation with *Agrobacterium*. The efficiency of regeneration response was markedly decreased by co-cultivation. One important aspect of the protocol developed was that the transformation frequency equaled the regeneration frequency in terms of the number of explants producing shoots following co-cultivation. The number of shoots per responding explant in transformed tissues was less but the shoot quality was good when compared to the untransformed explants where innumerable shoots that were often hyperhydric were observed (Sujatha, 2006).

2.5 Activity and Stability of Inheritance of the Gene, Adverse Effects on Growth, Yield, and Quality

The entry of any transgene in a plant cell is followed by its integration into the plant genome. The transgene along with reporter gene need to express in plant cell and this forms the basis for the transient assays. The coding sequence of bacterial enzymes can be assayed to study the transient expression in the transformed cells. These assays help in ascertaining the transformation efficiencies of the technique and help in developing stable integration systems. Some of the reporter genes commonly used are nopaline synthase (*nos*), chloramphenicol acetyltransferase (*cat*), bacterial or firefly luciferase (*luc*), *nptII*, and *gus*. The activity of the gene product can be assayed chemically, histochemically, or by using antibody techniques (Webb and Morris, 1992). For instance, Sankara Rao and Rohini (1999) studied GUS expression in *in vitro* regenerated shoots of safflower using a histochemical assay. As the GUS activity was confined to certain sectors, selection of GUS expressing shoots and calli was necessary. The activity of *nptII* was studied in total protein content of GUS positive shoots and calli by nondenaturing polyacrylamide gel electrophoresis (PAGE) assay. Transformation of safflower with *nptII* was confirmed when the total proteins of the GUS positive putative

transformants showed phosphorylated kanamycin at the expected position on the autoradiogram. The GUS protein was assayed by Western blot analysis using an anti-GUS antibody and a 74 kDa protein with the molecular weight similar to that of GUS protein was detected. Similarly, Rohini and Sankara Rao (2000) tested the transient expression of *uidA* gene in putative transformants from A-1 and A-300 varieties of safflower, after 4 days of postcultivation with *Agrobacterium* by Western blot analysis to identify transformed explants. At least four out of the 10 seedlings tested showed GUS gene expression. The immunostaining of the extracted immobilized proteins was done with GUS antibody. The integration and expression of the *uidA* gene in the putative transformants was confirmed by a 74 kDa protein band in Western blot analysis. Likewise, transient GUS expression was also checked by Orlikowska *et al.* (1995) and Sujatha (2006).

Enzymatic assay for the marker/reporter gene though indicate status of the cell as being transformed, yet is not an ample proof of the same, as some cells may have an inherent resistance to these drugs or might have acquired resistance during the process. Thus, assays such as PCR, Southern, Northern, and Western blot are used to confirm the integration of foreign DNA into plant genomic DNA and its expression (Schrammeijer *et al.*, 1990; Ying *et al.*, 1992; Knittel *et al.*, 1994; Schoneberg *et al.*, 1994; Orlikowska *et al.*, 1995).

PCR assays are done employing the primers for the incorporated gene. Thus, only those regions, which have the gene insert, get amplified. Orlikowska *et al.* (1995) confirmed stable integration of genes in four shoots out of six for *NPTII* gene and three out of six for *GUS* gene. Rohini and Sankara Rao (2000) carried out PCR analysis for checking the presence of 514 bp *uidA* and 800bp *nptII* genes. The PCR analysis of T₀ plants revealed genotypic variation in the transformation ability of varieties A-300 and A-1. Out of the two, A-1 was more efficient. The overall transformation frequency of A-1 was 5.3% compared to 1.3% for A-300. Out of ten plants of A-300, three plants contained *uidA* marker gene and five plants contained *nptII* gene. While, of the 24 A-1 plants analyzed, 14 contained *uidA* marker gene and 11 *nptII* gene. The absence of residual bacteria was confirmed when

amplification of *virC* primers was not detected in the DNA.

Southern hybridization is another confirmatory test for stable integration. It involves preparation of probe by radioactive or nonradioactive labeling of the inserted sequence, isolated by digesting the recombinant plasmid. The probe is hybridized with the isolated, restricted recombinant genomic DNA. The region where the probe hybridizes gives a signal, confirming the stable integration of the gene into the plant cell (Ying *et al.*, 1992; Orlikowska *et al.*, 1995). Sankara Rao and Rohini (1999) carried out dot blot analysis of the putative transformants. The membrane was hybridized with a $-^{32}\text{P}$ random prime labeled 2.1 kb fragment of the *uidA* gene. The *uidA* probe gave a strong signal after hybridizing with total genomic DNA of the transformants, indicating the presence of *uidA* gene. The study concluded stable integration of *uidA* and *nptII* genes in the transgenic shoots. However, the recovery of transgenic plants was a limitation as rooting of shoots was difficult. Similarly, Rohini and Sankara Rao (2000), used pUC-GUS121 from *Escherichia coli* strain XL-1 Blue for probe preparation. The plasmid carried a *uidA* gene with the CaMV 35S promoter and the Nos terminator. Digestion of the plasmid with *EcoRI* and *BamHI* restriction enzymes was reported to release a 2.1 kb fragment comprising the *uidA* coding region along with the Nos terminator. Southern analysis of the T₀ plants confirmed stable integration. The transgenes were inherited to the T₁ generation also. Four T₀ plants of A-1 yielded transformed progeny. However, the inheritance could not be confirmed due to small sample size (Rohini and Sankara Rao, 2000).

2.6 Specific Regulatory Measures Adopted

The risk assessment aims to identify and evaluate the potential adverse effects that a genetically modified organism (GMO) may have on the conservation and sustainable use of biodiversity in the receiving environments. The field trials and release of transgenic plants is monitored and regulated by global regulatory framework. These agencies ensure effective risk management that includes efficient monitoring systems, research programs, technical training, and improved domestic coordination amongst government agencies and services. The major issue

in risk assessment of transgenics is the possibility of gene escape to wild or weedy relatives which could have serious ecological and environmental bearings, such as aggressive weediness of the weedy relatives, possible loss of diversity, disturbance in ecological relationships with natural communities, unexpected phenotypic effects, etc. (Snow, 2002). Development of regulatory framework should involve quantification of gene flow from the developed transgenic to natural stands, understanding of population genetic structure of the recipient species, and estimate of spatial distribution of probable areas of gene flow (Bradford *et al.*, 2005).

The consideration should be given to both benefits and risks involved in the technology. Each country has different regulatory policy and stringency of these policies varies with the country. For instance, in the United States, the release of a new GMO requires scrutiny by four different federal bodies, namely, NIH (National Institute of Health), APHIS (Animal and Plant Inspection Health Service), FDA (Food and Drug Administration), and EPA (Environment Protection Agency). Each regulatory body has a different role to play. They monitor the development of GMO in laboratory, its trial, and finally its release in the market (Falk *et al.*, 2002).

APHIS had issued four release permits in the year 2005 to SemBioSys Genetics, Inc. for value added proteins in safflower. In one of the trials, SemBioSys Genetics, Inc. has conducted a field trial for its product, Immunosphere under the permit APHIS # 05-320-01r. The transgene in the developed product was evaluated by APHIS for the risk of the new plant pest introduction, impact on nontarget organism or on the threatened or endangered species, and was concluded by them that the DNA inserted into plant does not have an inherent plant pathogenic properties and shall not pose any rise. APHIS had set guidelines for quarantine and disposal of the transgenic material during and after the field trial. The guidelines clearly mentioned:

- Dedicated use of equipments for planting and harvesting to prevent any inadvertent transfer of transgenic material to other areas.
- A fallow 15.24 m (50 ft) boundary around the trial plot.
- Physical containment of the transgenic field trial from the sexually compatible species. The

site shall not have any compatible plant at least within 3.128 km miles periphery. Isolation of transgenic plants by at least 8.045 km miles from the conventional seed production site. Any accidental or unauthorized release of the transgenic material has to be reported to APHIS.

- Weekly monitoring of the test sites for weed, disease, and insects.
- Monitoring of the test site for safflower volunteers for at least two growing seasons after harvest (http://www.aphis.usda.gov/brs/aphisdocs/05_32001r.ndd.pdf).

Likewise, another permit was issued by APHIS for genetically modified safflower expressing one of the IgG binding domains present in native ProteinA expressed as fusion to oleosin (http://www.aphis.usda.gov/brs/aphisdocs/05_02502r.ndd.pdf).

3. FUTURE ROAD MAP

3.1 Expected Products

The edible oils yielded by members of Asteraceae are polyunsaturated, used as a cooking medium and are rich in linoleic acid. Though the oil is nutritionally rich, it is thermally unstable and turns rancid on exposure to air. Thus, in these oilseeds, incorporation of genes conferring high thermo stability and monounsaturations is highly desirable (Weiss, 2000).

The knowledge of seeds as protein reservoirs (Murphy, 1993) led Abenes *et al.* (1997) to test the *Arabidopsis* oleosin-GUS reporter fusion protein in *C. tinctorius*, *Brassica napus*, *Helianthus annuus*, *Ricinus communis*, and *Linum usitatissimum*. Though the expression in *C. tinctorius* was very low, the ingenious technique was later utilized by a Canadian Company, SemBioSys Genetics, Inc. for developing transgenic proteins of therapeutic as well as nutritional value (Seon *et al.*, 2002; Nykiforuk *et al.*, 2006; <http://www.sembiosys.com>).

SemBioSys Genetics, Inc. is the only company that has been able to grow transgenic safflower, which can produce insulin in seeds at commercial scale in Canada, the United States, Mexico, and Chile (<http://www.sembiosys.com>). Moloney *et al.* (2005; US Patent 2005/0039235 A1) describes

that to cater to the therapeutic protein demand of quarter of the earth population only 1000 ha of land is required, which would produce 2 t of the therapeutic proteins annually. In addition to insulin, SemBioSys Genetics Inc. is also involved in development of other pharmaceutical and nonpharmaceutical products in transgenic safflower, namely, Apo AI, Immunosphere, docosahexaenoic acid (DHA), gamma linoleic acid (GLA), etc. Apo AI is the major lipoprotein associated with high-density lipoprotein, which removes excess of cholesterol from arteries by reversing cholesterol transport. The anticipated product requirement to attain desirable results is 5–6 g of ApoAI per person. The company intends to achieve commercial levels of Apo AI expression in both *Arabidopsis* and safflower. They proposed to initiate clinical trials in 2007 and the product shall be launched by 2012 (<http://www.sembiosys.com>). Their another product, Immunosphere is an immunostimulatory protein-based feed additive, which imparts disease resistance to shrimp. This product is envisaged to cater to the problem of disease in shrimps which in turn is affecting US \$18 billion shrimp industry, across the world (<http://www.sembiosys.ca/Main.aspx?id=18>). In addition, SemBioSys Genetics, Inc. is developing a genetically engineered safflower, which could produce essential long chain polyunsaturated omega-3 fatty acid DHA. It is essential for the normal brain development in infants and is used in infant formulas. The company is expected to commercialize its product in 2009–2010 (<http://www.sembiosys.ca/Main.aspx?id=19>). Over and above, SemBioSys Genetics Inc. is engaged in developing GLA-rich transgenic safflower. GLA is an essential fatty acid used in topical, medical, food, and nutrition markets. The GLA-rich seeds shall be commercially produced by Arcadia Biosciences Inc. (<http://www.sembiosys.ca/Main.aspx?id=20>).

Nykiforuk *et al.* (2006) developed method for easy separation of proteins from other seed components using a simple technique of liquid–liquid phase separation. This separation process is highly cost effective compared to the number of chromatography steps. In an Information Systems for Biotechnology (ISB) news report, the company claimed that they were able to produce 1.2% insulin of the total

seed protein and this was envisaged to transform economics and scale of insulin production. Safflower-produced insulin could reduce capital costs compared to existing insulin manufacturing by 70 % and product costs by 40 %.

3.2 Addressing Risks and Concerns

Transgenic research has outpaced the understanding of its effect on the environmental factors, largely due to technology push revolution by the private laboratories. Their main objective is earning rich dividends by improving plant health and productivity. The gap in knowledge of their effect on environment remains unabridged (Batie and Ervin, 2001). There has been a growing concern over the food safety of the genetically modified crops. Based on the work done by WHO and Food and Agriculture Organization, Organization for Economic Cooperation and Development (OECD), an intergovernmental organization with members from 29 countries, proposed a concept of substantial equivalence. The concept recognizes the safety assessment of the product/organism derived through recombinant DNA technique in light of its similarities and differences with the analogous conventional product as a standard. It analyzes how the modified organism is different from the parent (Mayers *et al.*, 2002). It relies on the existing history of safe food use of a conventional food product and helps in safety assessment of GMO under conditions of similar exposure, consumption pattern, and processing practices.

The major environment risks are: (a) threat to genetic diversity and (b) transfer of transgenes, especially genes for resistance, to the wild and semi-domesticated relatives of safflower thus creating superweeds (Hall and McPherson, 2006). Two biosafety risks have been identified in field grown transgenic safflower. These are gene flow to cultivated safflower and to its wild relatives (Anonymous, 2006). The outcrossing in safflower and its wild relatives varies from 100 % to 0 % depending upon the environmental conditions, genotype, and the pollinator activity. However, the average is between 15 % and 20 % (Claassen, 1950). Though it is self-pollinated, insect pollination also takes place. However, the pollinators do not travel more than 10 km (Anonymous, 2006). Therefore, in addition to studying the distance pollen travels,

viability of the carried pollen under different conditions needs to be examined. McPherson *et al.* (2004) highlighted the relevance of these concerns especially with respect to genetically modified safflower because of compatible hybridization between cultivated safflower and its six wild relatives. The cultivated safflower belongs to the BB genome and all others members of this genome (*C. tinctorius*, *C. persicus*, *C. oxycantha*, and *C. palaestinus*) cross readily. The gene flow between the members has high probability if grown in vicinity (Knowles, 1980; Johnson, 2006). In addition safflower is used as bird seed and may also be carried away. This would mean entering of transgene into food chain through birds. Since safflower is grown as a minor crop in most of the countries, physical isolation would serve as one of the methods for confining crop-to-crop gene flow. Temporal confinement by putting up a barrier crop in the area surrounding transgenic cultivations is another possibility that can be explored (Anonymous, 2006). The outcrossing can be prevented by spraying the crop with an insect repellent or an insecticide. In addition, modeling of pollen movement by studying the behavioral patterns and the distances covered by the pollinators can also serve as an important tool. Studies are needed to understand gene flow, pollen viability, pollinator dynamics, and pollen/seed movement/dispersal (Anonymous, 2006). More information should be gathered on the outcrossing frequency, distance to the crop, feral safflower, and its weedy relatives. Moreover, these data should be of studies carried out for several years.

3.3 Expected Improvement in Transgenic Technology

The progress in transgenic research of safflower has been very slow, with only few reports on demonstration of development of transgenic safflower using antibiotic-resistance genes. So far, there has been only one successful report from a Canadian Company, SemBioSys Genetics, Inc., which is planning to launch its pharmaceutical and nonpharmaceutical products, in near future, using oleosin-fusion protein technology. The snail-paced progress has been observed to be primarily due to nonamenability of the plant material to the transformation procedures, inability of

the transformed tissue/sectors to regenerate and survival of the transformed plants. To overcome these shortcomings, concerted efforts are required to identify the candidate genes for carrying out value addition to the safflower oil for therapeutic, nutritional and industrial use, improvement in the current transformation techniques, improvement in the turn over rate of transformed plants by improving the overall efficiency of the regeneration and optimization of the survival conditions of the regenerated transformed plants. The future research areas in safflower would entail development of varieties/lines with modified fatty acid profile, thin hull, nonspiny, disease and stress resistance, oils with nutritional fortification, etc.

3.4 Specific Details for Intellectual Property Right (IPR)

Moloney *et al.* (2005) had obtained a US patent on the methods of insulin production in plants (US 2005/0039235A1). In the patent, they have provided a method for expression of human insulin gene in seeds. SemBioSys Genetics, Inc. has been able to achieve significant patent protection for oilbody/protein production.

1. INTRODUCTION

1.1 History, Origin, Botanical Description, and Taxonomy

The *Phaseolus* genus consists of more than 30 species, but only five (*P. acutifolius*, *P. coccineus*, *P. lunatus*, *P. polyanthus*, and *P. vulgaris*) have been domesticated (Debouck, 1999). The common bean (*P. vulgaris* L.) is the most widely cultivated species, occupying more than 85% of the total area cropped with *Phaseolus* throughout the world (Singh, 2001).

The diversity detected in *Phaseolus* species in relation to common bean is organized into primary, secondary, tertiary, and quaternary gene pools (Singh, 2001). The primary gene pool includes the modern and old cultivars, improved lines, and wild types of *P. vulgaris*. Within the primary gene pool, there is no intercrossing problems and normally includes the most cultivated species of the genus (*P. vulgaris*). The secondary gene pool consists of the species *P. coccineus*, *P. costaricensis*, and *P. polyanthus* (Broughton *et al.*, 2003). These three species intercross easily *inter se* and also cross with *P. vulgaris* without requiring embryo rescue, especially when the common bean is used as the female parent (Singh *et al.*, 1991). However, in some crosses partial sterility may occur in certain individuals, especially when the *P. vulgaris* is used as the male parent. The tertiary

gene pool consists of *P. acutifolius* and *Phaseolus parvifolius*, which are species that produce fertile progeny without requiring embryo rescue when intercrossed. Embryo rescue is required, however, when they are crossed to *P. vulgaris*. Normally, one or two backcrosses to *P. vulgaris* are needed to restore fertility. Again, the use of *P. vulgaris* as female, both in the cross and in the backcross with *P. acutifolius* increases the chance of obtaining fertile individuals in the segregant population. Fertile progeny is not obtained from crosses between the quaternary gene pool and *P. vulgaris*, even using the embryo rescue technique. This germplasm includes the *Phaseolus angustissimus* and *P. lunatus* species, which to date have not been proved to share genes and alleles with *P. vulgaris*.

There are approximately 30 300 *P. vulgaris* accessions in the germplasm bank at CIAT (International Center for Tropical Agriculture), of which approximately 29 000 are cultivated common bean accessions and 1300 are wild type. This bank also contains further 1000 accessions of secondary germplasm and more than 350 accessions of tertiary germplasm (Broughton *et al.*, 2003). There are thousands of other accessions of the primary, secondary, tertiary, and quaternary gene pools distributed in germplasm banks throughout the world. However, most of this variability has not yet been used directly in the common bean breeding programs (Miklas, 2000). The introgression and pyramiding of favorable

alleles between and within this germplasm could increase the genetic base of the segregant populations, maximize genetic gain from selection, and increase the stability of disease resistance incorporated in the new cultivars.

Although the common bean (*P. vulgaris*) dispersion process is not fully understood, there is a general agreement that its origin is in the American continent. Dispersion seemed to be noncentric, having started from Mesoamerica or South America, or independently from both regions. The agreement among specialists was reached after most evidence confirmed the theory (Singh, 1989; Singh *et al.*, 1991). The common bean dispersion process continued. It was taken to the old world by the Europeans after the discovery of the United States in the 15th century. The study by Vavilov (1951) supported the hypothesis of origin in the United States for the *Phaseolus* genus. The author showed that the center of genetic diversity of the common bean species *P. vulgaris*, *P. coccineus*, *P. lunatus*, and *P. acutifolius* is located in Mexico and Central America, because it is in this area that the largest diversity of forms of these species was found. A secondary center of genetic diversity was identified in a mountain area in Peru. Although the center of diversity and center of origin do not have the same meaning, the discovery by Vavilov was a strong indication in favor of the American origin of the common bean (Vieira *et al.*, 1999).

Morphological evidence showed that the wild-type bean, ancestor of the common bean, is extensively distributed in the United States, from West Mexico to Northeast Argentina, covering an almost continuous range of approximately 7000 km of mountain areas. Along this area, morphological differences that might affect the adaptation of the wild-type bean to contrasting environmental conditions were observed (Kami *et al.*, 1995). There are botanical differences among the wild beans found in Mexico and Central America (*P. vulgaris* var. *mexicanus*) and those in South America (*P. vulgaris* var. *aborigineus*). However, there are several traits (climbing plants, with a large number of small and dehiscent pods, with small, hard seeds that are difficult to germinate) that are common to the wild types but not to the cultivated forms (*P. vulgaris* var. *vulgaris*). This species underwent extensive modification in its characteristics during the domestication

process, and the current cultivars present a small number of flowers, pods, and seeds, which is a consequence of the smaller proportion of flowers that reach maturity compared to the wild types. In addition, modern cultivars have more restricted plant growth and more compact form, making them shorter and more erect; larger leaves; more robust stem; larger flowers, seeds and pods; fewer seeds per pod; seeds more permeable to water, that allows uniform germination and shorter cooking time; suppression of the seed dispersion mechanism; decrease in the percentage of fiber content in the pods and neutrality to photoperiod.

The wild beans cross easily with the modern *P. vulgaris* cultivars, producing fertile F₁ and F₂ generations, indicating that the wild and cultivated forms belong to the same species and no reproductive mechanism has emerged to isolate them. According to Singh (2001), the genetic differences between the two forms seem to affect only a small proportion of loci, specifically the occurrence of the *D1-1* gene in the Middle American and *D1-2* in Andean wild and cultivated populations.

Studies on the domestication and organization processes of the common bean genetic variability was first based on morphological traits and biochemical markers. In the late 1980s, after the discovery of polymerase chain reaction (PCR) methodology, a number of molecular marker technologies have been developed. The direct analysis of DNA variation allowed a more precise estimation of the genetic variation that can be accessed at the nuclear and/or organelle genomes, enabling the investigation of different aspects of the genetic structure of crops species. The characterization of genetic diversity among common bean accessions from divergent gene pools using molecular markers, has been shown to be effective to elucidate mechanisms of origin and evolution of common beans, to investigate the effects of domestication process in the reduction of the genetic diversity that has characterized common bean gene pools, and to allow an efficient management and effective exploitation of the germplasm (Gepts, 2004). These studies have been performed using molecular markers that access specific genetic polymorphisms at a known or anonymous DNA sequence site, including random amplified polymorphic DNA (RAPD) markers that showed to be effective to identify

ances within the Mesoamerican gene pool (Beebe *et al.*, 2001), the use of amplified fragment length polymorphism (AFLP) markers that showed to be effective to assess the level and direction of gene flow between wild and domesticated bean populations (Papa and Gepts, 2003) and the analysis of variability at specific translated genomic regions that allowed to conclude about the level of diversity between wild and domesticated common beans (McClellan *et al.*, 2004). More recently, using microsatellite markers (simple sequence repeat, SSR), new findings where the intrapopulation diversity of the Andean gene pool was higher than within the Mesoamerican gene pool groups was reported by Blair *et al.* (2006a), opening new perspectives for the exploration of the genetic variability at the Andean gene pool.

Over the last years, several research groups have made efforts in the development of microsatellite markers for common bean, those are considered the most informative class of markers. Microsatellites, that present the advantages to be co-dominant, multiallelic, and PCR-based, were initially derived from GenBank sequences by Yu *et al.* (1999, 2000), followed by Guerra-Sanz (2004) and Blair *et al.* (2003). Methods of microsatellite discovery based on enriched genomic libraries were developed by Gaitán-Solís *et al.* (2002), Yaish and Pérez de la Vega (2003), and Buso *et al.* (2006). The development of SSR markers derived from bacterial artificial chromosome (BAC) was conducted in common beans by Caixeta *et al.* (2005).

Johns *et al.* (1997) studied the genetic variability in the common bean domestication centers using RAPD markers and morphological traits. The authors reported that their RAPD markers were capable to screen the genotypes into well-defined groups, which corresponded to the Mesoamerican and Andean domestication centers, whereas the morphological markers were less efficient in identifying the origin of the germplasm. The indication is that these data of diverse nature are representing different portions of the total variability because they probably suffered distinct evolutionary pressures. According to Gepts (1991) this apparent paradox was related to the different type of gene actions that control these markers. Some common bean morphological traits are controlled by genes with large phenotypic effect and are thus subject to human selection. On

the other hand, biochemical and molecular traits rarely have a marked effect on the phenotype and are less likely to suffer selection. Consequently, the chance of perpetuating mutations in biochemical and molecular traits is smaller than the chance of maintaining mutations that cause large morphological alterations, which affect the total variability accessed by each one of these markers.

1.2 Economic Importance

Common bean is an important source of protein in the diet of more than 300 million people throughout the world. It is especially important in tropical and subtropical developing countries, with significant regional variations concerning taste and grain type preference. The grains have high protein content, high quantity of complex carbohydrates, fiber, oligosaccharides, and phytochemicals, and are also an important source of iron, phosphorus, magnesium, manganese, and to a lesser extent zinc, copper, and calcium (Broughton *et al.*, 2003).

The common bean grain quality traits include low dietary fiber content (6%) compared to other products such as wheat (10.5%), maize (9%) (Juliano, 1993), soybean meal (20.6%), oat flakes (6.5%) (Cozzi and Lajolo, 1991), but a greater content than brown rice (4%) (Juliano, 1993). A quantity equivalent to one cup of common bean supplies at least half of the daily requirement of folic acid, which is especially important during pregnancy. It also supplies 25–30% of the recommended daily requirements of iron, 25% of magnesium and copper, and 15% of potassium and zinc.

The composition of the common bean (*P. vulgaris* L.) grains provides several health benefits for human nutrition. The grains are indicated in the dietary treatment of several diseases such as heart diseases, diabetes mellitus, obesity, and cancer (Geil and Anderson, 1994). Beans are a good source of food fiber, especially soluble fiber (Kutos *et al.*, 2003). The consumption of soluble fiber-rich foodstuffs has efficiently decreased total cholesterol serum levels and, consequently, reduced cardiovascular diseases in the population (Glore *et al.*, 1994).

There are 119 producing countries in the world if all genera and species included as

common beans in the FAO statistics (FAO, 2004) are considered. The common bean (*P. vulgaris*) is the most widely cultivated species of the *Phaseolus* genus. FAOSTAT places world common bean production at around 22 million tons cropped in approximately 35 millions ha. Only 10 countries account for approximately 70% of the world production; India is the largest producer with 14.31%, followed by Brazil with 13.39%, Nigeria (10.4%), Myanmar (7.58%), and Mexico (5.25%). Only 15% of the total common bean production worldwide is exported, with five countries accounting for 80% of the market: China 21%; Myanmar 27%; the United States 10%; Canada 9%, and Argentina 13% (FAO, 2004).

1.3 Traditional Breeding of Common Bean

1.3.1 Objectives in common bean breeding

A sustainable plant breeding program must envisage the prebreeding, breeding, and postbreeding stages of cultivar development. Extra effort can be directed to a specific stage requiring greater progress at any point of time. The breeding and postbreeding stages normally receive most attention in a common bean cultivar development program. On the other hand, the prebreeding stage has been neglected, in part due to the need for interdisciplinary work, better qualified human resources, high costs, and long-term returns. Strong prebreeding programs can contribute to the synthesis of new promising broad genetic base populations, to the identification of potentially useful genes and alleles. It would also enhance knowledge of the germplasm of the species and help establishing nuclear collections to ensure continuous gains in the plant breeding programs.

The objective of most breeding programs is to increase yield and guarantee yield stability at a production cost that maximizes the economic returns to the farmers. Under favorable conditions, yield increases through breeding are achieved by accumulating alleles that maximize biomass production and foster efficient assimilate distribution. In unfavorable environments, stable yield and reduced production costs can be obtained through breeding for tolerance to biotic and abiotic stresses that cause yield losses. Regarding the biotic stresses, diseases cause the most losses

and, therefore, always deserve special attention in the major breeding programs. In addition to improving the level of resistance to the most common disease pathogens that cause anthracnose, common bacterial blight (CBB), rust, angular spot, and common mosaic, a breeding program is also expected to develop stable resistance to pathogens of potentially dangerous new diseases, for example, *Curtobacterium* blight, scab (caused by *Colletotrichum truncatum*), Asian rust and soil diseases, especially white mould, root rot, and wilts. There is the challenge of obtaining resistance to the *Bean golden mosaic virus* (BGMV) and to the *Bean golden yellow mosaic virus* (BGYMV).

The fact that common bean cropping has become an important agricultural business changed the relative importance of the cultivar traits to the farmers. Growers currently seek cultivars with erect plant canopy (with pods that do not touch the soil, with short guides and closed branching) to allow mechanical harvesting, with low loss indices, and high grain quality. Cultivars must also allow good plant aeration in the field and decreased disease incidence. Earliness has become an important trait for growers, since it allows larger flexibility in the cropping system management, greater water and electricity economy in irrigated crops, and better chance of escaping seasonal droughts, insects, and diseases, and also gives a faster return on invested capital. The ever more frequent water shortage problems associated with the greater likelihood of paying for irrigation water indicate that drought tolerance has become an essential trait for future common bean cultivars. Movement of common bean cropping areas to higher temperature regions and the emerging problem of global warming have prompted the breeding programs to work on the development of high temperature tolerant cultivars. There are large common bean areas cropped under drought and high temperature conditions, where the subsistence family agricultural system predominates and the common bean plays a fundamental role in the food safety of millions of people. Genotypes adapted to these conditions must be developed.

The consumer demand for common bean grain showing higher nutritional, organoleptic, and functional quality has made this area of research a priority for some genetic breeding programs in the world. The most common agents

that affect mineral bioavailability are phytates, tannins, fibers, polysaccharides, and oxalates. The polyphenols (tannins) and phytic acid are part of the antinutritional compounds found in the common bean, and may be involved in the development of the hard-to-cook effect (Hohllberg and Stanley, 1987), which increases cooking time, decreases palatability, and reduces protein digestibility (Reyes-Moreno and Paredes-López, 1993). Polyphenol compounds, which consist of polyphenol acids and their derived substances, affect the nutritional quality of foodstuffs and their biochemical and physiological properties. These polyphenol substances are also partially associated with the changes that occur in the grains during storage, and play an important role in the development of postharvest grain hardening (Bhatti, 1990; Shomer *et al.*, 1990). Mineral availability, especially iron, is affected by the presence of tannin and dietary fibers. Commercial acceptance and consumption of common bean grains are influenced by an irreversible darkening of the grain tegument that depends on the cultivar and occurs gradually after harvesting. Prolonged storage periods, especially at high temperatures and relative humidity, considerably increase the cooking time and darkening of the grain. These characteristics are also influenced by the environment, as shown in the study carried out by Michaels and Stanley (1991) with 20 common bean cultivars in three different locations. Breeding for grain quality has long been reported (Meiners and Litzenberger, 1975; Ghaderi *et al.*, 1984). Current research has shown the possibility of decreasing the common bean antinutritional factors, such as phytates and phytic acid, and has identified the presence of wide variability within the species (Coelho and Lajolo, 1993; Kigel, 1999).

1.3.2 Common bean breeding: tools and strategies

The increase in yield potential of the common bean (*P. vulgaris*) crop has been gradual and low, in spite of the broad variability present for most traits, including grain yield (Nienhuis and Singh, 1988). One of the main reasons for this low increase in yield potential has been the consumer market requirement for different commercial grain types according to regions.

This requirement has reduced the germplasm resources used and limited the genetic variability available in the breeding programs. Also, the tendency of breeding new cultivars with erect stem with fewer ramifications has added to the difficulty of increasing the yield potential of modern cultivars. The use of genetically similar genotypes has become more evident after studies by Singh (1988, 1989), who grouped the common bean germplasm into 12 genetic pools and later further grouped them into six races (Singh *et al.*, 1991), indicating that breeders have traditionally carried out hybridization involving materials predominantly from a single gene pool. Singh (1988) observed that the variability for grain yield and its primary components and other agricultural traits was greater among than within gene pools. Similar result was also obtained by Abreu *et al.* (1999) assessing several agriculturally important morphological traits in common bean.

The genetic diversity studies of wild common bean ancestors measured by DNA markers suggest a considerable index of diversity spread within and among the gene pools (reviewed by Blair *et al.*, 2006a). In contrast, the genetic diversity of cultivated common bean is thought to be smaller than that of wild common bean due to a genetic bottleneck that occurred during crop domestication, dispersal from center of origin, and selection for specific traits (Gepts, 2004; Papa *et al.*, 2005). The introgression of valuable genetic variants from wild ancestors of common bean by means of applying marker-assisted backcrossing or genetic transformation strategies can help in broadening the genetic base of the elite breeding gene pool, increasing the chances of genetic gains in the breeding programs.

The use of genotypes from different gene pools as parents in crosses to obtain segregant populations increases the probability of obtaining genetic combinations with greater yield and production stability potentials. Singh (1988) reported that crosses between cultivars stemming from gene pools from the same center of origin and presenting similar growth habit and seed size showed greater frequency of desirable recombinants. This is probably due to the fact that crosses between very divergent parents can lead to low adaptation of the segregant population and, consequently, difficulties in the selection process. Theoretically, crosses between cultivars

from different gene pools but from the same center of origin should contribute to increase gain from selection, especially when adapted parents are used. More recently, an advanced backcross population derived from a cultivated Andean genotype and a Mesoamerican wild accession of common bean was developed and the results showed that this strategy was advantageous, since no fertility barriers were observed between the wild and cultivated gene pools, the derived lines themselves were close to commercial type, and new diversity for plant vigor and tolerance mechanisms were incorporated into the cultivated background (Blair *et al.*, 2006b). These findings opened new perspectives for the introduction of allelic variants from nonadapted genotypes into cultivars with modern traits, such as seed types and plant architecture.

Kelly *et al.* (1997) proposed a hierarchical pyramidal system with three levels of germplasm improvement for common bean. Germplasm movement is from the base to the top as gene accumulation for yield in specific genotypes occurs. Therefore, at the pyramid base the breeder works with several limiting factors using the full genetic variability present in the poorly adapted, wild type, interracial, and interspecific germplasm; at the intermediate level the number of limiting factors is restricted, but the breeder still uses considerable levels of genetic diversity; and at the top of the pyramid, elite germplasm breeding is carried out, involving agriculturally and economically acceptable materials within each commercial grain type.

A breeding program for common bean should be structured to meet the demand of growers and consumers of the new cultivars. The breeder should make use of the genetic diversity of the available germplasm, of the knowledge of the problems of the growing regions and of the knowledge of problems that might occur with the establishment of the crop in the different production systems and growing seasons. The selection criteria should emphasize well-defined regional demands such as preference for grain type, which includes characteristics such as size, color, shape, shininess, and cooking quality, and allow association of desirable traits during the development of inbred lines superior to the cultivars traditionally in use. The intent of increasing production to supply the external market has required breeding of special common bean types with large grains,

aiming at increasing product acceptance in the international market with higher aggregated value and differentiated price.

Common bean germplasm shows high levels of variability in grain type and size. However, the market requirements for grain type, as already commented, and the need for resistance to disease have limited selection progress through restrictions to germplasm utilization and to the number of progeny advanced, therefore increasing the genetic vulnerability (Smale, 1997; Abreu *et al.*, 1999) of the crop. Recurrent selection is a breeding method that has been used in common bean and has enabled the development of superior lines, without reducing the genetic variability. Because it involves a cyclic process of recombination and selection, yield alleles accumulate in segregant populations while maintaining high variability for other traits offering the breeder ways of exploiting immediately this variability by obtaining new inbred lines at each selection cycle. Recurrent selection in inbred species involves the stages of base population formation, endogamous family assessment and selection followed by recombination of the superior families. Ramalho *et al.* (1988) suggested that breeders using this breeding method should be aware of the following points: (1) parents used to form the base population should be divergent but should also express good phenotypes for the greatest number of traits of interest; (2) recombination will be efficient if the best families to be intercrossed are identified. In this case, recombination certainly will contribute to increase the frequency of favorable alleles in the population; and (3) selection of individual plants is not efficient, mainly if the trait has low heritability. Selection should be based on endogamous families assessed in replicated experiments. The general rule is to carry out a recombination cycle at every two generations of assessment; the first assessment in a single location, because of the small quantity of seeds, and the second in at least two locations. Therefore, superior family selection in each assessment cycle can be based on the joint analysis of the generations and locations.

The common bean haploid genome is considered one of the smallest among the legumes (Zheng *et al.*, 1991), estimated at 450–650 Mbp (mega base pair) (Bennett and Leitch, 1995) and has 11 chromosomes. According to Vallejos *et al.* (1992), in common bean the mean ratio

of the physical distance compared to the map distance is 530 kbp cM⁻¹. As the common bean genome has approximately 637 Mbp, it is estimated that the total size of the map of this species would be around 1200 cM. Several reports in the literature have demonstrated the efficient use of DNA markers to construct informative linkage maps with high coverage for common beans (for more details, see review by Miklas and Singh, 2007). In the early 1990s, genetic maps for common bean based mainly on co-dominant restriction fragment length polymorphism (RFLP) markers (Chase *et al.*, 1991; Vallejos *et al.*, 1992; Nodari *et al.*, 1993a), dominant RAPD markers (Adam-Blondon *et al.*, 1994) and combination of different classes of markers (Freyre *et al.*, 1998) were constructed. In recent years, due to the increasing number of microsatellite that became available, these markers have been extensively mapped in common beans (Yu *et al.*, 2000; Blair *et al.*, 2003, 2006a). The availability of high-density linkage maps based on a set of co-dominant multiallelic microsatellite markers will lead to the construction of an integrate linkage map for common bean allowing more precise positioning of markers, widely distributed across the genome, minimizing the occurrence of large interval without markers. These maps will expand the prospects of making comparative analysis, turning more real the advancement in quantitative trait loci (QTLs) detection, establishment of synteny and validations across different mapping populations, increasing the potential use of these linkage maps among the research groups. In addition, these co-dominants mapped makers could be placed on the corresponding BAC clones, that are already available for beans (Kami *et al.*, 2006), allowing us to probe insights into the aspects of the genome structures and organization of the *P. vulgaris* genome, to make an assessment of the correspondence between the physical and genetic distances and also to define physical intervals of desirable genome sequences in order to sequence and clone them.

Following the construction of linkage maps, genomic regions involved in the control of simple as well as complex heritable traits are being identified. QTL for important traits of interest have been detected in the genus *Phaseolus* using a variety of molecular marker classes and several types of segregating populations (Frei *et al.*, 2005;

Beebe *et al.*, 2006; Blair *et al.*, 2006b; Miklas *et al.*, 2006). A wide range of quantitatively inherited traits, such as domestication syndromes related traits, complex disease resistance traits, phenological traits, plant architecture, seed weight and yield components, where generally a few major genes control large proportion of the total variation, have been identified (Koinange *et al.*, 1996; Park *et al.*, 2001; Tar'an *et al.*, 2002; Blair *et al.*, 2006b). The experimental approaches used have been showed to be effective to successfully identify genomic regions that have a significant effect on the expression of QTLs and provide information about the number and the magnitude of the effects of the traits.

However, it should be pointed out that the identification of an important QTL in a particular genetic background and in a specific environmental condition may not be assumed to all genetic backgrounds and locations. When the genotypes are assessed in more than one location, year and/or cropping season, forming different environments, there is a possibility to identify and estimate the genotype by environment interaction (G × E) effects. There are several studies on common bean (Ramalho *et al.*, 1988; Takeda *et al.*, 1991; Melo *et al.*, 1997; Tar'an *et al.*, 2003) that report strong G × E effects for the main traits used in breeding in this species. Melo *et al.* (2002, 2004) and Teixeira *et al.* (2005) studied the QTL × environment interaction and ascertained that this interaction was significant for all the analyzed traits (flowering time, reaction to powdery mildew, angular spot, seed size, plant architecture, and grain yield), and the correlation among the means of the families in the different environments was mostly low, indicating that in the common bean the phenotypic expressions, and therefore that of the QTLs, depended strictly on the environment and on its specific interaction with each family of the population. Since in the common bean crop, G × E interaction is highly significant due to the diversity of cropping locations and seasons (environments) used, most QTLs are expected to suffer the effect of this interaction, and be expressed only under specific conditions. However, some stable QTLs that maintained their significant effects across more than one environment and were consistent with QTLs from previous studies in common beans, were reported (Melo *et al.*, 2002, 2004; Teixeira *et al.*, 2005) for days to flowering

and seed weight traits (Park *et al.*, 2000; Blair *et al.*, 2006b).

Most of the traits of agricultural importance are controlled by multiple genes, with small individual effects, subjected to a pronounced environmental effect, and dependent of the genetic background. Significant progress in map construction and QTL identification has been reported for common beans in recent years. A large set of microsatellite markers has been made available and, in addition, the growing pool of expressed sequence tag (EST) sequencing for *P. vulgaris* genome (Ramírez *et al.*, 2005) is making available molecular markers based on expressed sequences that could facilitate the direct establishment of probable relationships between candidate genes and specific QTLs through the development of a transcriptional map, opening the interesting opportunity to test these markers in association mapping experiments. To date, the molecular data generated could not be yet effectively used into the breeding programs. Progress on mapping experiments based on genetically more informative markers with a broad and regular genome coverage will support to look for useful homologies of QTL regions across independent crosses also helping to better elucidate aspects of the architecture of the important QTLs and also contributing to increase the map information mainly for traits that do not segregate within a single population (Brondani *et al.*, 2006). Furthermore, informative markers associated to QTLs controlling traits of interest will allow to explore, in an efficient and effective way, the allelic variation at these QTLs opening new perspectives for expanding the gene pool of cultivated common beans and identify potentially and useful source of genetic diversity to be introduced into the *P. vulgaris* cultigen.

As expected by breeders, the use of these markers will help particularly in the selection process to identify lines with desirable phenotypes, which are expressed in most of the environments, thus contributing to the increase in the efficiency of the common bean breeding programs.

1.3.3 Successes in common bean breeding

Common bean production takes place with several problems of biotic and abiotic origins. Common biotic problems are diseases caused by fungi,

bacteria, and virus, and damage from insect and nematode attack. The most common abiotic problems are low soil fertility, especially deficiencies in nitrogen, phosphorus and zinc, and toxicity from aluminum and manganese. Drought is also one of the most generalized abiotic problems affecting common bean yield in all producing regions of the world, especially in the Brazilian northeast, the central and northern Mexican highlands, East Africa, and the intermountain regions of the United States, where it causes production losses (Singh, 2001). Breeding programs have worked to increase tolerance to biotic and abiotic stresses to indirectly increase common bean yield potential and reduce sensitivity to environmental adversity. However, there is another line of work to directly increase the common bean productive capacity by increasing its productive potential in optimum management conditions, that is, under conditions of low environmental stress.

Yield increase in most crops can be attributed to the genetic gains obtained through improved cultivars, to better cropping technologies and agricultural practices, and also to the improvement of cropping environments. It is a combination of these factors that facilitate maximum yield per unit of area. Frequently, improved cultivars have been the main factor for yield increase and have provided the stimulus to adopt better agronomic and agrichemical practices, leading to an additional increase in yield (Singh, 1992).

1.3.4 Limitations of conventional breeding and potential of genetic engineering

Some of the challenges of common bean breeding are more difficult to overcome due to restrictions imposed by limited genetic variability within the species and also due to difficulties in trait assessment. One typical example of limitation is the low genetic variability for resistance to the common BGMV in Brazil, for sources of resistance is almost nonexistent. The BGMV and BGYMV, which occur in the main common bean producing areas in Latin America, are transmitted by the whitefly *Bemisia tabaci* Gen., and have been especially important in the dry growing season (Morales and Anderson, 2001; Morales, 2006). Annual crop reductions in the range of 90 000–280 000 tons, amount sufficient to feed

6000–20 000 adults, are estimated. In addition to the economic problems caused by yield reduction, this virus also brings other social consequences, since it precludes common bean cropping in family based agricultural systems. Approximately 180 000 ha are currently not apt for common bean cropping in the dry season in Brazil, due to the occurrence of BGMV. These areas can be returned to the productive process after cultivars with adequate resistance level are available. Although there have been advances in scientific knowledge, technological results with direct application for growers have not been achieved, suggesting that further research and adjustments of procedures are required in several areas. Immunity reaction to both the viruses has not yet been found in *Phaseolus* spp. accessions evaluated by national and international research institutions. Tolerance to the disease is controlled by polygenes and, therefore, difficult to be efficiently transferred to commercial cultivars (Pessoni *et al.*, 1997; Park *et al.*, 2001). However, literature reports on the genetic control of tolerance to BGMV are sometimes conflicting, with some authors also suggesting monogenic (Blair and Beaver, 1993) or oligogenic control (Blair *et al.*, 1993). There are also reports of cultivars that usually show certain degree of tolerance to the disease, but become susceptible and suffer severe yield losses when submitted to high infestations of the insect vector. This fact is aggravated by the failure of natural control measures and by the high cost of chemical control.

Regarding the implementation of marker-assisted selection (MAS) to supplement the common bean breeding programs for disease resistance, in the last decade, with the advantage and accessibility of the molecular marker technology, a number of markers for traits related to the major disease resistance with significant impact in the common bean agriculture have been successfully identified, as extensively reviewed by Miklas and Singh (2007). A list of markers linked to specific genes conditioning resistance to several pathogens causing bean diseases has been released for CBB, anthracnose, angular leaf spot, BGYMV, and bean rust (Kelly *et al.*, 2003). Markers linked to these major genes can be used to trace the presence of target genes through MAS procedures, where the genotype carrying the target allele is, by indirect way, selected for

the desirable phenotypes. Once important genes are tagged with a marker, selection in successive backcross generations are performed in order to select individuals in the progeny that possess a marker allele from the donor parent, improving the efficiency and facilitating introgression of the resistance genes into elite common bean genotypes (Oliveira *et al.*, 2002). However, due to the constant appearance of new races of a pathogen, there is a necessity to constantly incorporate new resistance genes into bean lines and cultivars. This problem has been partially overcome by the pyramiding of multiple genes for prevalent pathogen races into selected cultivars with MAS strategy, in order to achieve durable resistance. Lines resistant to angular leaf spot carrying resistance genes derived from selected cultivars were developed by Oliveira *et al.* (2005). In addition, advanced Mesoamerican bean lines with “Carioca-type” grains (Ragagnin *et al.*, 2005) and black and red bean cultivars (Costa *et al.*, 2006) have been developed with multiple disease resistance genes also through marker-assisted strategies. However, although significant progress has been made, some limitations for the extensive use of MAS as routine in the common bean breeding program still remain. As early pointed out by Kelly and Miklas (1998), the main limitations of success of MAS are: (1) the genomic sequence related to the marker is not sufficiently close to the resistant gene allowing that it segregates independently during the recombination; (2) most of the markers tightly linked to the target genes are not universal in all genetic backgrounds, making their utilization restricted to the population where the genes were mapped; (3) new races of the pathogens evolve constantly in different environments and, in addition, the pathogens rapidly overcome the resistance of the gene identified; (4) new cultivars with advantageous agronomic attributes are currently being released and the MAS process should be individually performed for each of the accession, taking time for the introduction of the desirable allele.

Drought tolerance in common bean, as in others crops, has dramatic consequences on production, mainly in developing countries, reducing the grain yield in more than 1.5 million ha of cultivated area in the world (Teran and Singh, 2002). Drought tolerance is considered as an example of a trait difficult, expensive, and inaccurate to assess,

because of the complexity of the environmental control. Water shortage is the climatic factor that contributes the most to harvest frustrations. Low crop yield due to water shortage in greater or lesser intensity is frequently reported in most of the common bean cropping regions. Flowering is the most vulnerable stage, followed by the grain filling period. In Brazil, common bean grown from January to April is highly constrained by water shortage, which leads to low and unstable yield. Considering that 44% of the Brazilian production is in this period, it is recommended that new cultivars adapted for sowing from January to April should be developed. As a part of the Generation Challenge Program initiative, phenotyping sites are being structured in Brazil in order to characterize genetic materials at the phenotypic level, testing for adaptability for drought tolerance and the effects on the productivity. The availability of these sites will allow several studies on drought phenotyping in common bean.

Regarding the potential of molecular markers to improve drought tolerance in common bean, there is available today a large set of drought tolerance QTLs and candidate genes previously identified for model crops, such as rice (Vinod *et al.*, 2006). These can be used as a starting point to search for homologous genes in other species, like *P. vulgaris*. Once candidate genes are identified, one of the ways to evaluate their association with the trait of interest is using the approach of association mapping studies, where the informative markers potentially identified as associated to drought tolerance traits could be used in MAS. Projects are being conducted in maize, rice, and beans, also as a part of the Generation Challenge Program initiative. All strategies discussed until now are related to common bean genetic variability to drought tolerance. However, other genes, alleles, promoters, etc., related to drought tolerance, are constantly being identified in other species, however, crossing barriers prevent their direct transfer by hybridization. Therefore, genetic engineering could be a powerful tool to obtain common bean cultivars more tolerant to drought.

2. BEAN GENETIC ENGINEERING

Several methods have been developed for inserting genetic information into plant cells, such as

Agrobacterium-mediated system, direct DNA uptake into protoplasts and particle bombardment. Due to the advances in the methodologies for gene delivery and plant tissue culture, it was assumed that plant transformation would become a routine for most important crops. Unfortunately, legumes, in particular common bean (*P. vulgaris*), became one of the greatest challenges to transformation efforts. Indeed, the ability to genetically engineer common bean is still not trivial (Aragão and Rech, 2001; Svetleva *et al.*, 2003; Popelka *et al.*, 2004; Veltcheva *et al.*, 2005).

Early efforts to transform common beans demonstrated its susceptibility to *Agrobacterium*, and some transgenic tissues or organs, such as calli, leaves, meristems, cotyledon, and hypocotyl have been achieved (Lippincott *et al.*, 1968; McClean *et al.*, 1991; Franklin *et al.*, 1993; Becker *et al.*, 1994; Lewis and Bliss, 1994; Brasileiro *et al.*, 1996; Nagl *et al.*, 1997; Karakaya and Ozcan, 2001). Mariotti *et al.* (1989) reported production of transgenic bean plants through utilization of the *Agrobacterium* system. However, there was no molecular evidence for genetic transformation or progeny analysis. Transient gene expression using either electroporation or polyethylene glycol (PEG)-mediated protoplast transformation was demonstrated (Crepý *et al.*, 1986; Bustos, 1991; Leon *et al.*, 1991; Giovinazzo *et al.*, 1993). Dillen *et al.* (1995) demonstrated the applicability of electroporation of intact tissue to introduce and express the *gus* gene in bean embryonic axes. A gene transfer system has been recently developed by Liu *et al.* (2005) using sonication and vacuum infiltration-assisted *Agrobacterium*-mediated transformation for Kidney beans, without any tissue culture step.

During the last two decades, efforts to achieve an efficient methodology for bean transformation were obstructed due to the lack of an efficient tissue culture system to regenerate bean plants from transformed cells. Numerous attempts have been made to regenerate bean plants from several types of isolated cells and tissues. Although no satisfactory results have been achieved, some methodologies have described shoot organogenesis (through multiple shoot induction) of the apical and axillary meristems from bean embryonic axis (McClean and Grafton, 1989; Malik and Saxena, 1992; Mohamed *et al.*, 1992, 1993). Cruz de Carvalho *et al.* (2000) employed the transverse thin

cell layer (tTCL) method to optimize the frequency of shoot regeneration without an intermediate callus stage. The same authors also showed that addition of 10 μM silver nitrate (AgNO_3) to the medium with benzylaminopurine (BAP) enhanced the number of shoots that developed per explant and increased shoot elongation.

2.1 Transformation Methods

The particle bombardment method was initially proposed by the group of John Sanford (Cornell University) with the objective to introduce genetic material into plant genome (Klein *et al.*, 1987; Sanford *et al.*, 1987). Since 1980s, the universality of application of particle bombardment has been evaluated, demonstrating to be an effective and simple process for the introduction and expression of genes in to bacteria, protozoa, fungi, algae, insects, mammals, plants, and isolated organelles, such as chloroplasts and mitochondria (Daniell *et al.*, 1991; Carrer *et al.*, 1993; Klein and Fitzpatrick-McElligott, 1993; Sanford *et al.*, 1993; Vainstein *et al.*, 1994; Bogo *et al.*, 1996; Rech *et al.*, 1996). The basis of the particle bombardment method is the acceleration of DNA-coated microprojectiles (particles of tungsten or gold) at high speed (about 1500 km h^{-1}) toward living cells. After penetration in the cell, the DNA dissociates from the projectiles and integrates into the chromosomes. Several devices (particle guns) have been constructed in order to accelerate these microprojectiles. All these systems are based on the generation of a shock wave with enough energy to move the microprojectiles. The shock wave can be generated through: a chemical explosion (Sanford *et al.*, 1987), discharge of gas helium (Sanford *et al.*, 1991; Finer *et al.*, 1992; Takeuchi *et al.*, 1992), vaporization of a drop of water through the electric discharge with high voltage and low capacitance (McCabe *et al.*, 1988) or low voltage and high capacitance (Rech *et al.*, 1991), discharge of compressed air (Morikawa *et al.*, 1989).

Particle bombardment allowed the bombardment of intact plant cells facilitating possible transformation of plants for which a regeneration system was not available. The status of *Phaseolus* tissue culture was well reviewed by Nagl *et al.* (1997), Svetleva *et al.* (2003), Popelka *et al.* (2004) and Veltcheva *et al.* (2005).

Although several authors have claimed the achievement of *P. vulgaris* regeneration, so far, only cytokinin-induced shoot organogenesis was obtained. Multiple shoots are formed in the peripheral regions of the apical meristem (Aragão and Rech, 1997). Induction of shoot formation in bean meristems can be achieved by culturing the mature embryos in the presence of cytokinins such as kinetin, zeatin, and BAP (Kartha *et al.*, 1981; Martins and Sondahl, 1984; McClean and Grafton, 1989; Franklin *et al.*, 1991; Malik and Saxena, 1992; Mohamed *et al.*, 1992, 1993; Araújo and Rech, 1997; Delgado-Sánchez *et al.*, 2006). Compounds such as thidiazuron (TDZ) and N-(2-chloro-pyridyl)-N'-phenylurea (CPPU) that possess cytokininlike effects have also been tried (Mohamed *et al.*, 1992).

Consequently, the apical region of embryonic axes became an obvious target for the development of a system based on the bombardment of meristematic cells. Early experiments showed the applicability of particle bombardment for introduction and transient expression of genes in apical meristematic cells (Genga *et al.*, 1991; Araújo *et al.*, 1992, 1993; Russel *et al.*, 1993). However, how deep the particle could penetrate in order to reach the cells that could generate transgenic plants has yet to be determined. The different parts of meristem have been divided into layers (L1, L2, and L3). The layer L1 is the most external and forms the epidermis of the differentiated regions. The layers L2 and L3 divide preferentially in the anticlinal and periclinal planes to form the organs. Several studies have demonstrated that the differentiated *de novo* shoots are originated from the subepidermal layers (L2 and L3) of the apical meristem. However, the L1 layer could participate in their formation (McClean and Grafton, 1989; Franklin *et al.*, 1991; Malik and Saxena, 1992; Mohamed *et al.*, 1992). The shoots are formed in the peripheral regions of the apical meristem (Aragão and Rech, 1997). The bombardment of *P. vulgaris* meristematic cells showed that it was possible to efficiently reach these layers, demonstrating that it would be possible to achieve transgenic plants (Aragão *et al.*, 1993; Figure 1).

Russel *et al.* (1993) were able to achieve transgenic navy bean (cv. Seafarer) plants using an electrical particle acceleration device. It was

Figure 1 Bean transformation via microparticle bombardment. (a) Embryonic axes expressing the *gus* gene 24 h after bombardment. (b–c) Scanning electron micrograph showing the morphology of the shoot apical meristem regions of two varieties presenting the apical dome exposed (b) and partially covered by primordia leaves (c). (d) Transmission electron micrograph showing tungsten microparticles (arrows) penetrating up to the third cell layer from the meristematic apical region. (e) Transgenic shoot developing from a multiple shooting apical meristem. (f) Leaves from transgenic plantlets (right) and control (left). Bars represent 100 μm in b and c, and 2 μm in d

the first report of *P. vulgaris* transformation, presenting molecular evidences of transgenic progeny. However, the frequency of transgenic plants obtained was much lower (0.03%) and variety limited. In addition, the tissue culture protocol described was time consuming, involving several

temperature treatments and medium transfers of the bombarded embryos before recovery of transgenic shoots. Kim and Minamikawa (1996) achieved transformation bombarding embryonic axes, obtaining stable transformed bean plants (cv. Goldstar).

Figure 2 Occurrence of chimerism during the process of obtaining transgenic shoots from particle-bombarded apical meristematic region (a). Chimerical transgenic branch (b), leaf (c), and root (d) presenting *gus* gene expression

A reproducible system to achieve transgenic bean plants routinely was developed. The bean transformation system was also based upon the development of a tissue culture protocol of multiple shoot induction, shoot elongation and rooting (Figure 1). The average frequency of transformation (the total number of putative transgenic plants divided by the total number of bombarded embryonic axes) was 0.9% (Aragão *et al.*, 1996; Araújo and Rech, 1997). In addition, they have been able to transform several varieties of *P. vulgaris*, including those that were considered recalcitrant to transformation in previous studies. Molecular analysis and progeny test of several generations of transgenic lines revealed the presence of a small number of integrated copies of the foreign genes and segregation in a Mendelian fashion in most of them. This is extremely important in order to accelerate the introduction of these plants in a breeding program as well as the production of transgenic commercial varieties.

The shoots regenerated from the bombarded meristematic apical region may include all, some,

or none of the cells that received the transgenes. Consequently, undesirable periclinal, mericlinal, or sectorial chimeras can be produced in the adventitious shoots (Figure 2). Chimeric organs have been observed in transgenic common bean plants, such as leaves and roots (Figure 2). This limitation could probably be removed by using a more appropriated selection agent. It is difficult to have an efficient selection for transformed cells because only a few cells from the meristem are transformed and generally cannot be reached by the selective agents. Although antibiotics and herbicides, such as kanamycin and glufosinate ammonium (GA) have been used (Aragão *et al.*, 1996, 2002), this selection is not efficient. Recently, this group has developed a novel system for selecting transformed meristematic cells based on the use of imazapyr, a herbicidal molecule capable of systemically translocating and concentrating in the apical meristematic region of the plants. This selectable marker coupled with an improved multiple particle bombardment protocol, resulted in a significant increase in the

recovery of fertile, transgenic material compared with standard soybean transformation protocols (Aragão *et al.*, 2000). This selection system is being successfully used to introduce genes into dry bean and chimerical plants have not been observed.

Genetically modified common bean have also been obtained by using linearized vectors (Vianna *et al.*, 2004; Bonfim *et al.*, 2007). Although the frequency of transformation is lower (0.2–0.6%), the use of linear vectors is important to eliminate undesirable antibiotic selective genes.

Particle bombardment has been considered a universal method to introduce macromolecules into any living cell, not limited by genotype or variety (Sanford, 1990). However, the morphology of the explants utilized during bombardment may greatly influence the successful recuperation achievement of transgenic bean plants (Aragão and Rech, 1997). In some cultivars, the embryonic axes revealed the apical meristematic region partially exposed, whereas only the central region could be visualized (Figure 1). The number of meristematic cells, which could be reached by the microparticle coated-DNA, will be drastically reduced. Consequently, the efficiency of transformation could also be reduced. Several studies have shown that *de novo* shoot differentiation in embryos of bean grown on cytokinins appeared in the peripheral layers of the meristematic ring (McClellan and Grafton, 1989; Franklin *et al.*, 1991; Malik and Saxena, 1992; Araújo and Rech, 1997). Thus, based on these concepts, cultivars with a nonexposed apical meristematic region are not suitable for transformation using particle bombardment, considering that removal of the leaf primordia is not practical.

Although the common bean is susceptible to *Agrobacterium*, only recently stable transformation mediated by *Agrobacterium* was demonstrated. Liu *et al.* (2005) reported the development of an *Agrobacterium*-mediated transformation system based on sonication and vacuum infiltration of *Agrobacterium tumefaciens* (LBA4404) into germinated kidney bean embryos (var. Green Light). Inoculated germinating seeds of kidney bean were sown in soil pots and from a total of 525 surviving plants, 16 were transformed (Liu *et al.*, 2005). The transgenes were detected up to the second generation.

2.2 Introduction of Useful Traits

The methionine-rich 2S albumin gene from Brazil nut (*be2s1* gene) was the first agronomically important gene expressed in common bean tissues (Aragão *et al.*, 1992). Mature embryos were transformed in order to have transient expression of a methionine-rich albumin gene from Brazil nut (*be2s1* gene), which could be detected by Western blot and enzyme-linked immunosorbent assay (ELISA), 24 h later (Aragão *et al.*, 1992). Further, stable genetically engineered common bean lines containing the *be2s1* gene were obtained aiming to improve the methionine content in the seeds. The transgene was stable and correctly expressed in homozygous R₂–R₆ generations. In two of the five transgenic lines, the methionine content was significantly increased by 14% and 23% over the nontransgenic plants (Aragão *et al.*, 1999). However, 2S albumin from Brazil nut was identified as an allergen (Nordlee *et al.*, 1996; Koppelman *et al.*, 2005). Indeed, transgenic soybean containing the Brazil nut 2S albumin was allergenic to patients. Consequently, the development of a transgenic common bean variety with improved methionine content was aborted.

Russel *et al.* (1993) introduced the *bar* gene that confers resistance to the herbicide phosphinothricin and the coat protein gene from bean BGMV in an attempt to achieve virus-resistant plants. The introduced *bar* gene showed to confer strong resistance in transgenic bean plants to the herbicide in the greenhouse. However, bean plants containing the BGMV coat protein gene did not show resistance to the virus (D. Maxwell, personal communication).

The 5' regulatory sequences from several genes have been transient and stably studied in bean tissues transformed using the particle bombardment. Regulatory regions from the seeds specific promoter from Brazil nut 2S gene were studied in bean embryos (Grossi de Sá *et al.*, 1994; Vincentz *et al.*, 1997). Transgenic bean plants were produced containing the β -glucuronidase gene (*gus*) under the control of the canavalin gene promoter (Con A) from jack bean. Either the organ and maturation stage-specific promoter regulation was studied in seeds of transgenic plants (Kim and Minamikawa, 1996, 1997).

Transgenic bean lines containing the *bar* gene, which encodes phosphinothricin acetyl

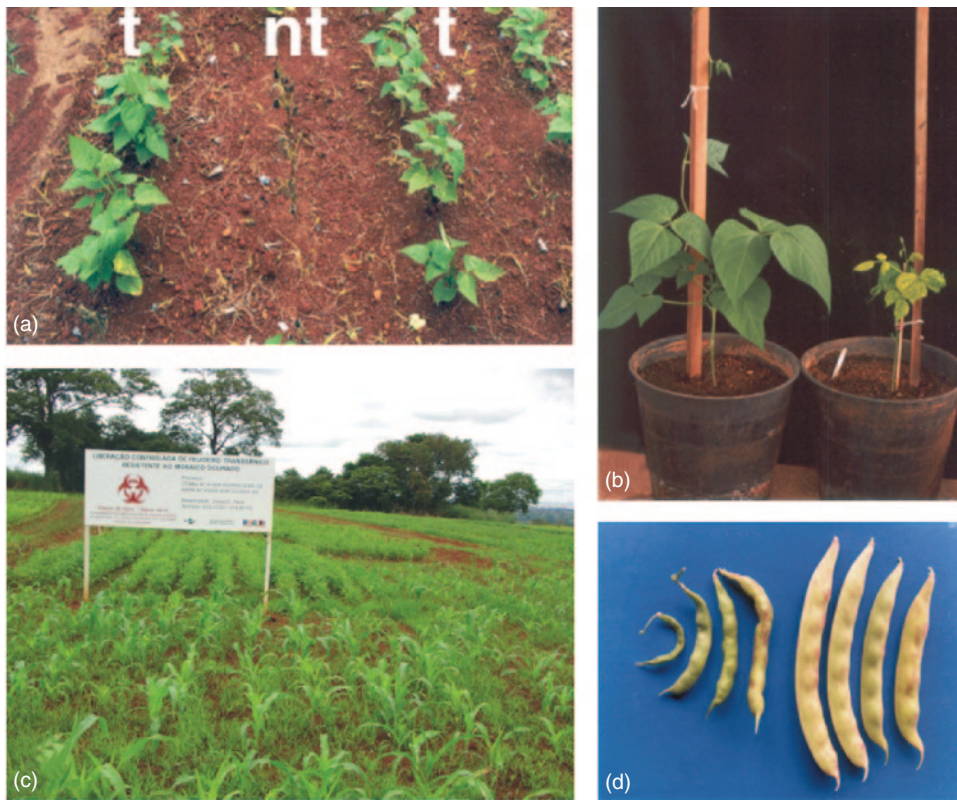

Figure 3 Field trials with genetically modified common bean plants. (a) Transgenic lines (t) tolerant to 400 g ha⁻¹ of glufosinate ammonium compared to a nontransgenic line (nt) treated with the herbicide. (b) Transgenic plants resistant to the BGMV (left). (c) Lines resistant to BGMV being tested in the field. (d) Effect of virus infection on pods of nontransgenic plants (right) and transgenic (left) plants, both inoculated

transferase, and resistant plants to the herbicide GA were generated (Russel *et al.*, 1993; Aragão *et al.*, 2002) and tested in field (Aragão *et al.*, 2002; Figure 3). Two transgenic events were tolerant to 500 g ha⁻¹ of GA, under green house conditions, with no visible symptoms and developmental growth. Field evaluation has shown that the plants tolerated up to 400 g ha⁻¹ of GA (Aragão *et al.*, 2002; Figure 3).

In order to obtain common bean plants resistant to BGMV, the genes *Rep-TrAP-REN* and *BCI* from the virus were cloned in antisense orientation under the control of the CaMV 35S promoter and used to transform bean. Two transgenic lines were obtained both of which had delayed and attenuated viral symptoms (Aragão *et al.*, 1998). Using the strategy of transdominance, transgenic bean lines were obtained with a vector contained

the mutated *rep* (*ACI*) gene from the BGMV. The mutated *rep* gene codes for a mutated AC1 (REP) protein with amino acid codon change in the putative NTP-binding motif (D262R). One line exhibited resistance to the virus. However, the resistance was studied during several generations and depended on the inoculation level (Faria *et al.*, 2006). More recently, the concept of using RNA interference (RNAi) construct to silence the *ACI* viral gene has been explored to generate highly resistant transgenic common bean plants (Bonfim *et al.*, 2007). Eighteen transgenic common bean lines were obtained with an intron-hairpin construction to induce post-transcriptional gene silencing against the *ACI* gene and one line exhibited high resistance (approximately 93% of the plants were free of symptoms) upon inoculation at high pressure (more than 300 viruliferous whiteflies per

plant during the whole plant life cycle) and at a very early stage of plant development.

Transgenic kidney bean plants were obtained expressing a group 3 LEA (late embryogenesis abundant) protein gene (*ME-leaN4*) from *Brassica napus* (Liu *et al.*, 2005). Plants showed enhanced growth ability under salt and water stress. The increased tolerance was also reflected by delayed development of damage symptoms caused by drought stress. In addition, transgenic lines that presented high level of *ME-leaN4* gene expression showed higher stress tolerance than lines with lower expression level (Liu *et al.*, 2005).

2.3 Field Evaluation

Studies on the behavior of transgenic common bean plants under field conditions have been conducted. The first field trial was carried out from November 2000 to February 2001 in Distrito Federal, Brazil to evaluate the resistance of the T₂ generation of an event tolerant to glufosinate ammonium (Aragão *et al.*, 2002; Figure 3). Since then, several transgenic lines resistant to the BGMV have been evaluated in the field at Embrapa Rice and Bean (Goiás, Brazil) (Figure 3). In these studies, it is appraised the interactions of the transgenic plants with microorganisms, insects, and others plants from of the agricultural and natural environment. Moreover, the stability of foreign genes expression, gene flow, and factors related to their interaction with the complex physiology of these plants exposed to natural stress in tropical are being evaluated. Furthermore, food biosafety analysis is being carried out by the Biosafety Network from Embrapa to determine differences in nutritional and antinutritional compounds as well as verify presence of toxic molecules.

3. FUTURE PROSPECTS

Several species of the genera *Phaseolus*, such as *P. coccineus*, *P. acutifolius*, and *P. angularis* (Nagl *et al.*, 1997), have been regenerated in the *strictu sensu*, e.g., plants regenerated *de novo* from undifferentiated cells originated from differentiated cells. The extrapolation of these technologies to *P. vulgaris* would be a breakthrough toward

the development of a transformation system to accelerate the generation of new transgenic commercial varieties. The ideal system seems to be the regeneration of fertile mature plants through somatic embryogenesis or organogenesis, preferentially from mature embryonic axes, which has been considered the most adequate tissue for transformation either by *Agrobacterium*, electroporation and particle bombardment. The improvement in the bean transformation technology is essential for obtaining a larger number of transgenic lines, increasing the probability to select transformation events presenting the desirable phenotype. Depending on the introduced trait, only one of 30–40 independent transgenic plants obtained has the desirable transgene expression without undesirable characteristics, such as multiple transgene loci and nontransference of the foreign genes to the first generation.

Since the first report of transformation of *P. vulgaris* in 1993, a few groups have transformed bean to introduce useful traits. Difficulties that still exist in obtaining transgenic plants might account for this fact. Nevertheless, during the last two decades, efforts to achieve efficient methodologies for regeneration and transformation of common bean plants advanced. In parallel, the availability of characterized genes (coding and regulatory sequences) has increased as a direct result of several structural and functional genomics projects in plants.

An increased understanding of common bean genome associated with contributions from biotechnology will provide an opportunity for breeders to accelerate the development of new varieties with valuable agricultural traits. Common bean has a relatively small genome of about 630 Mb with 11 haploid chromosomes and genomics studies are in progress because of its social and economic value (Vallejos *et al.*, 1992; Blair *et al.*, 2003; Broughton *et al.*, 2003; Nodari *et al.*, 1993b; Pedrosa *et al.*, 2003). The Phaseomics project (<http://www.phaseolus.net>) was started in 2001 by an international consortium of laboratories with an aim of developing high yielding bean varieties that have high protein quality and are stress and disease resistant. They plan to initially sequence large scale ESTs from different tissues of *P. vulgaris*, which will be followed by sequencing, and analysis of the bean genome. At this moment, about 47 300 nucleotide sequences from

genus *Phaseolus* are released (about 26 200 from *P. vulgaris*) and these numbers are increasing rapidly. These facts generated an excellent scenario for introduction of useful traits as well as study gene function in *P. vulgaris* plants. There is a considerable interest in the introduction of genes for several useful traits in common bean, such as virus, insect, bacteria, and fungi resistance, environmental stress tolerance, and improve nutritional properties. In addition, manipulation of plant architecture and phenological characteristics might facilitate management, increasing yield, quality, and diversity. Several traits might be manipulated by genetic engineering, such as plant life cycle and the transition from vegetative to reproductive growth, controlling flowering time. Indeed, several genes controlling phenotypical traits have already been cloned and characterized in distinct organisms. This information can be used to either express heterologous genes or suppress the expression of homologous genes in common bean plants. Biotechnological tools complement those from classical breeding and have the potential to accelerate the generation of new varieties containing genes from agronomic traits, which are difficult to be found in the primary or secondary gene pool.

1. INTRODUCTION

Legumes provide high-quality protein food for people, protein-rich fodder for livestock, and fixed nitrogen for the soil. In Africa, all three are in short supply. And in Africa, where it took its origin as an agricultural crop, cowpea (*Vigna unguiculata* var. *unguiculata*) (L.) Walp.) is the most important legume, at least in terms of economics (Langyintuo *et al.*, 2003). Cowpea is also known as blackeye pea, southern pea, frijole, lubia, feijao caupi, and niébè. One of its distinguishing features is its adaptation to the hot, low-and-erratic rainfall climates of the Sahelian and Sudanian zones in Africa. Historical records of the domestication of cowpea are sparse, but it may have been domesticated and spread as a crop together with sorghum and pearl millet (Steele, 1976). Today, over much of its range in Africa it is still widely grown in the traditional way, intercropped with sorghum, millet, maize, or cassava. Cowpea grown in monoculture may be increasing as farmers begin to realize its potential as a source of cash income. It is mainly grown by low-resource farmers who prize it for its ability to yield well on poor soil with a minimum of moisture—as little as 300 mm annually. In addition to providing food and fodder

it is a cash crop sold by women growers in local markets and by increasing numbers of commercial farmers in the ancient and substantial regional trade system. For Africa, which includes about 80% of the cowpea growing area of the world (Langyintuo *et al.*, 2003), there are potential—but almost completely undeveloped—export markets in South America and Europe.

There are good reasons for the economic importance of cowpea; one of them being the excellent nutrition it offers. At different places and times in Africa the grain, the green pods, the dried leaves, and hay all command good market prices. One factor driving demand is the high-quality protein it offers. On average, the grain contains about 23–25% protein by weight. Dried cowpea foliage is likewise protein rich, offering on a dry weight basis levels similar to the grain (Ohler *et al.*, 1996). In many parts of Africa, fresh tender green cowpea leaves picked before flowering are the first part of the crop harvested. These leaves provide needed protein during the period Africans call the “hungry time” (“lokotchin yinwa” is the name for it in the Hausa language). This is the time when the harvest of the previous year has been sold or consumed and food is scarce before the next harvest comes in.

In parts of East Africa, there is a substantial commercial market for dried leaves, and in the Sahel, cowpea hay sometimes commands very high prices. In Senegal in recent years green pods have become very popular as a cash crop; women selling basins of green pods dot the roadsides when the pods are maturing in the fields. In addition to protein, cowpea grain is an excellent source of bulk carbohydrate (CHO); indeed, in this regard it is nearly as good as cereals, containing roughly 60% CHO by weight, principally starch. Cowpea grain also offers key vitamins including thiamin, riboflavin, ascorbic acid, niacin, and folic acid. It is low in fat, containing about 1% by weight, and it represents a fair source of fiber at about 6%. It is relatively low in sulfur amino acids but high in lysine and other essential amino acids, making it a good complement to the mainly cereal diets. Thanks to the nutrition it offers, cowpea has been considered by the US National Aeronautics and Space Administration as a possible space station crop (Ohler and Mitchell, 1992).

Cowpea provides excellent ground cover and so helps to preserve precious moisture in the semi-arid zones where it thrives. Thanks to its ability to fix nitrogen (Bado *et al.*, 2006), it adds substantially to soil fertility as well.

Investment in cowpea research and extension has been modest-to-poor at best. This is partly because it has always been mainly a crop of impoverished regions, with sub-Saharan West Africa and northeastern Brazil being by far the major cowpea-growing areas of the world. African governments, which might be expected to invest in cowpea improvement in their own self-interest, have largely neglected it. This neglect was easy in the case of cowpea—widely known as “poor man’s meat”—because cowpea is regarded as a crop of poor people and is mostly grown by women farmers who have little political influence. Several international agencies have helped to advance the cause of cowpea research, particularly the International Institute of Tropical Agriculture (IITA), which has the mandate among the International Agriculture Research Centers (IARCs) to work on cowpea, and; the United States Agency for Agricultural Development (USAID)-supported Bean/Cowpea Collaborative Research Support Program (CRSP), which has worked on cowpea improvement since 1980. Charitable donors have also played an important part, among the most prominent being

the Rockefeller Foundation and, more recently, the Kirkhouse Trust. An informal group of scientists called the Network for the Genetic Improvement of Cowpea for Africa (NGICA) was formed in 2001 to push all aspects of cowpea improvement. Among NGICA’s achievements was the promotion of the use of the tools of biotechnology for the genetic improvement of cowpea. Toward that end NGICA also helped convince the new African Agriculture Technology Foundation—an African public–private partnership designed to facilitate access by African farmers to technology from technology providers through royalty-free licenses and agreements—to incorporate *Bt*-cowpea as one of its projects.

1.1 History, Origin, and Distribution

Cowpea was domesticated in Africa, presumably in the northeastern part of the continent in present-day Ethiopia. The progenitor of the modern cultivated *V. u. unguiculata* is probably the wild annual form, *V. unguiculata* var. *spontanea*. In support of the idea that the crop originated in northeastern Africa, Steele (1976) noted that the variability of the wild relative *V. unguiculata* spp. *dekindtiana*—which has also been considered as a possible progenitor of cultivated cowpea—is greater in that part of Africa than in West Africa. Pasquet and Baudoin (2001) likewise support a Horn of Africa origin based on ethnobotanical, linguistic, as well as phytogeographical considerations. Still, some scientists have considered West Africa a possible site of origin because of the high variability of *V. u. dekindtiana* in this region (Faris, 1965). Lack of archeological records for cowpea cultivation hinders efforts to establish its site of origin unequivocally. Like its New World relative, common bean, cowpea may prove to have two or more sites of origin. The current consensus seems to be that domesticated cowpea originated in the northeastern region of sub-Saharan Africa (cf. Smartt, 1985) and spread westward and southward from there. This Horn of Africa origin is also supported by recent studies using molecular markers (Ba *et al.*, 2004).

1.2 Botanical Description

The taxonomy of domesticated cowpea (*V. unguiculata* var. *unguiculata*) has a history of

revisions, changes, and modifications that leave the nonexpert perplexed. The pantropical genus *Vigna* forms part of the subfamily Papilionoideae under the family Fabaceae (Leguminosae). Cowpea belongs to the subgenus *Vigna*, section Catiang. It is genetically isolated from other *Vigna*, which includes only one other distinctly African species, bambara groundnut (*V. subterranea*). There are several Asian *Vigna* crop species such as urdbean (*V. mungo*), mothbean (*V. aconitifolia*), and mungbean (*V. radiata*). Morphological, ethnographical, molecular and other criteria led Pasquet (1999) to a classification of *V. unguiculata* that recognizes 11 subspecies, 10 of which are perennial and one of which (cowpea) is annual. Annual cowpea has two forms, the cultivated *V. unguiculata unguiculata* var. *unguiculata* and the wild/weedy form *V. u. u.* var. *spontanea*, both of which are inbreeding. *V. u. u. spontanea* is typically found only near the borders of cultivated cowpea fields and within them.

The 10 perennial *V. unguiculata* subspecies include (i) some that are exclusively outcrossing: subspecies *baoulensis* (A. Chev.) Pasquet, ssp. *burundensis* Pasquet, ssp. *letouzeyi* Pasquet, ssp. *aduensis* Pasquet, and ssp. *pawekiae* Pasquet, and (ii) others that are both outbreeding as well as inbreeding: ssp. *dekindtiana* (Harms) Verdc., ssp. *stenophylla* (E. Mey) Verdc., ssp. *tenuis* (E. Mey) Marechal, Mascherpa, and Stainier, ssp. *alba* (G. Don) Pasquet, and ssp. *pubescens* (R. Wilczek) Pasquet. Pasquet (personal communication to LLM) points out that the number of subspecies is likely to change as additional living material becomes available for study and as new molecular characterization tools are applied.

Originally only three, then later four cowpea cultigroups were recognized (Baudoin and Marechal, 1985). A fifth has recently been added (Pasquet, 1998). Smartt (1985) accounted for the emergence of two of the cultigroups on the basis of selection practiced in Asia after cowpea reached that continent, probably via India, about 2000 years ago. The cultigroups are: (1) Unguiculata, the African cowpea treated here, (2) Biflora, an erect woody perennial grown for fodder and seed, (3) Sesquipedalis, grown for its long, succulent pods in the Far East, (4) Textilis, cultivated in northern Nigeria and Niger; it has long peduncles, and is grown for the textile fibers it provides, (5) Melanophthalmus, originally from West Africa, is

able to flower quickly under inductive conditions; the seeds have thin and often-wrinkled testa (Pasquet, 1998).

The growth habit of cowpea ranges from indeterminate to determinate. As regards plant architecture, there is great variability. Plants range from erect, semi-erect, and prostrate (spreading, creeping) to climbing. One of the key features of cowpea is its long tap root, which enables the plant to obtain moisture at depths that cannot be reached by most plants.

The cowpea genome is estimated to be 613 Mb distributed amongst 22 chromosomes. In this regard, it closely resembles the model leguminous plant, *Medicago truncatula* (also estimated at 613 Mb) (Arumuganathan and Earle, 1991). The sequencing and analysis of whole genomes of model plants, such as *Arabidopsis thaliana*, have paved the way for orphan crops like cowpea, where far fewer resources are available for research (Mahalakshmi and Ortiz, 2001). Fortunately, the Kirkhouse Trust, a Scottish Charity established by Sir Ed Southern, has recently committed resources to enable detailed molecular characterization and genetic improvement of cowpea. Thanks to Kirkhouse, the cowpea genome is now being sequenced. The sequencing approach is known as Gene Spacing under the trade name GeneThresher^R (<http://cowpeagenomics.med.virginia.edu>). It exploits a fundamental difference between active (transcribed) and inactive DNA, namely that inactive DNA sequences are methylated and active ones are nonmethylated. By cloning genomic DNA into a methylation-sensitive bacterial host the sequences that are not methylated are the only recombinant clones recovered. By this means only the active DNA is selected for sequencing. In a preliminary study conducted by the University of Virginia and Orion Genomics in 2004 using GeneThresher^R, Michael Timko and colleagues (Timko, 2006) achieved a fourfold enrichment of the original 600+ Mb of DNA resulting in only 150 Mb of active DNA to be sequenced. Sequencing of the 150 Mb is expected to result in at least 95% of the entire transcribed sequences of cowpea being described. Application of this new technique should accelerate the development of genetically improved cowpea varieties and strengthen the molecular breeding efforts currently underway to introgress desirable traits using markers.

Complementary to this are efforts underway by the Generation Challenge Program involving

the IITA and collaborators. They are developing expressed sequenced tags (ESTs) for simple sequence repeats (SSRs) and single nucleotide polymorphisms (SNPs) in cowpea to be used in marker-assisted breeding. The IITA project may pool its efforts with those of the International Livestock Research Institute (ILRI) project on the development of germplasm for livestock nutrition using genomics (Crouch and Ortiz, 2004; <http://www.generationcp.org>). Feltus *et al.* (2006) recently used the conserved-intron scanning primers (CISPs) approach to study conserved sequences and comparative genomics in orphan crops. Unfortunately cowpea was not one of the crops chosen for study.

Cytological studies help us understand the underlying genetic factors that govern interspecific compatibility. Adetula *et al.* (2005) as well as others have attempted to make wide crosses between domesticated and wild *Vigna*, especially *Vigna vexillata*, in the hope of accessing new sources of genes for insect resistance and other needed traits. *V. vexillata*, like *V. unguiculata*, has a diploid genome with 22 chromosomes. Adetula and colleagues identified satellite DNA on chromosome 2 and demonstrated this chromosome to be highly variable, thereby lending itself to serve as a marker for breeding. More recently, however, Adetula (2006) found that in 20% of the cells under study, the mitotic chromosome number of *V. unguiculata* ssp. *dekintiana* var. *pubescens* (TVNu110-3A) was actually 23, confirming a previous study (Adetula, 1999) where the meiotic chromosome number had been determined. Polytenic chromosomes occur in highly specialized tissues of some angiosperms and are indicative of high metabolic activity (Carvalheira, 2000). In plants, they are found in only a few species and appear to be limited to the ovaries and immature seed tissues. Within cowpea the polytenic chromosomes observed in anther tapetal cells were reported to be 3.5 times larger than those found in mitotic cells (Guerra and Carvalheira, 1994). *In situ* hybridization using both radioactive and nonradioactive labeling has been used to identify, visualize, and localize these chromosomes. Fluorescent *in situ* hybridization (FISH) was used in *V. unguiculata* to detect and localize DNA in anther tapetal cells (Guerra, 2001). Furthermore, utilization of polytenic chromosomes helped in the identification of the 45S ribosomal DNA sites in both *Phaseolus coccineus*

and *V. unguiculata*. This led, more importantly, to the identification of an even larger number of 10 ribosomal DNA sites in cowpea and to the suggestion that perhaps this increase in sites in *Vigna* over *Phaseolus* could have arisen by gene conversion (Galasso *et al.*, 1995, 1999).

1.3 Economic Importance

Cowpea is today grown throughout the world, with the most intense production in the northern savannahs of sub-Saharan Africa, with Nigeria and Niger the leading producers. According to Langyintuo *et al.* (2003), some 10 million hectares are under cowpea cultivation worldwide, with the sub-Saharan Africa cowpea belt producing about two-thirds of the annual world yield. Total annual grain production is about 3.7 million tons. The second largest production area after Africa is Brazil, where the crop is well suited to the relatively low rainfall and poor soils in the northeastern part of the country. Cowpea is also grown in marginal areas of eastern and southern Africa, especially in Sudan, Somalia, Mozambique, Botswana, and southern Zimbabwe. Cowpea is mostly grown as an intercrop with cereals, but little of that harvest reaches regional markets. The most important export market for cowpea in West Africa is Nigeria, simultaneously the world's largest cowpea consumer as well as producer. There is significant cowpea production in the Mediterranean, South Asia, and in the southern and southwestern United States.

Total world harvested area of cowpea in the 1990s was 9 738 000 ha, 7 804 000 of which was produced in only 12 nations in West and Central Africa. The greatest production (1 691 000 tons) was in Nigeria, followed by its neighbor to the north, Niger, with 359 000 tons (Langyintuo *et al.*, 2003). The importance of cowpea as a nutritional complement to the mostly cereal and root-and-tuber-based diets of West and Central Africa has resulted in an ancient cowpea trade system. Demand for cowpea is particularly high in Nigeria. Its dense population and large oil revenues create enormous effective cowpea demand by both urban and rural consumers. Cowpea markets in West Africa link the humid coastal zones with the semi-arid interior. In essence, cowpea produced in the drier regions (northern Nigeria, Niger, Burkina

Faso, northern Ghana, northern Cameroon, etc.) flows southward toward or into Nigeria, the most populous of the African nations. This pattern of cowpea trade toward the Gulf of Guinea has been given the name “Nigerian Grain Shed”. A second, smaller trading geography is found to the west. The Senegalese Grain Shed occupies Senegal, Mauritania, and parts of Mali.

In West and Central Africa, grain marketing is organized through formal and informal channels. Formal market places are subject to government control. Informal markets are not officially recognized but still operate well, though outside of government control. An informal market may be nothing more than a group of women or men who meet to carry out a transaction in a village or at a roadside. Farmers who are constrained by liquidity or transportation may accept quick transactions and lower prices compared to the generally prevailing market prices. Farmers usually sell their cowpeas to rural assemblers, who in turn sell them to urban wholesalers directly, or through intermediaries. Wholesalers sell large stocks when prices are high enough to pay for transaction costs (procurement, storage, and handling) plus a profit margin. They may also be involved in trade of other commodities, such as cereals and groundnut.

There is no reliable source of year-to-year cowpea production or marketing data in Africa. Information on cowpea marketing and trade is scarce and data on cowpea production economics are scattered, because marketing research has focused on African export crops such as cocoa, coffee, cotton, and groundnut and to a lesser extent cereals (Van der Laan cited by Langyintuo *et al.*, 2003).

In West Africa, protein products traditionally move south from the drier areas to the more equatorial humid areas, while carbohydrate products move north. Thus, it is that cowpea is also traded from West to Central Africa because of the comparative advantage that the drier areas of West Africa have in protein production—cowpea being a major source of protein (Langyintuo *et al.*, 2003). At least 285 000 tons of cowpea are shipped among countries in the region each year. This is probably an underestimate because the official sources for this estimate did not collect data on all formal and informal flows of grain. In 1998, Burkina Faso imported about 8000 tons from Niger and exported a total of 5500 tons to Togo,

Côte d’Ivoire, Ghana, and Benin. It is estimated that Nigeria’s average annual imports of 260 000 tons per year from Niger accounts for about 73% of Niger’s surplus production. Cowpea trade between Nigeria and Benin is bilateral. Togo and Ghana, and Ghana and Benin trade bilaterally as well. Gabon depends on Cameroon, Togo, Benin, and Nigeria for cowpea. Mauritania, Gambia, and Guinea Bissau rely on Senegal (Langyintuo *et al.*, 2003; INPhO (FAO), 2007).

1.4 Cowpea Losses Due to Pests and Diseases

Insects are the major causes of crop losses in cowpea. In some years and areas, grain yields can be reduced to nearly zero, if the crop is not sprayed with insecticide. Aphids, flower thrips, legume pod borers (*Maruca vitrata*), and a complex of pod-sucking bugs each and collectively cause yield losses. In northern Nigeria, for example, untreated cowpea plots yielded 76 kg ha^{-1} , while fields treated with the carbamate insecticide Carbaryl (at 1.12 kg ha^{-1}) yielded 1382 kg ha^{-1} . Similar yield increases were seen after treatment with chlorinated hydrocarbons (Raheja, 1976).

The insect problems of cowpea are not limited to the field. When the harvested grain is subsequently stored, beetles of the family Bruchidae (*Callosobruchus maculatus*) cause major losses—estimated at US\$ 30 million annually in Nigeria alone (Ogbuinya, 1997). The insect problems of cowpea are compounded by the fact that chemical insecticides not officially approved for cowpeas (e.g., cotton insecticides) are often used on them anyway, both in the field as well as in storage. Concerns about the negative ecological and health consequences of such insecticide use—although not yet systematically surveyed for cowpea—are growing in the minds of the farmers themselves, and the problem of insecticide misuse has begun to catch the attention of scientists, extension agents, and policy makers (James *et al.*, 2003). Murdock (2002) pointed out that traditional methods and chemical insecticides have largely failed to stop insect-caused losses. In addition to their high cost and uncertain availability, insecticides require sprayers, proper protection practices, and training for (i) effective use and (ii) to lower the health and pollution

hazards. Murdock (2002) states that “If we decided to solve the problem of insect control in cowpea solely by using insecticides, we would have to spray insecticides at probably a minimum of 250 g of insecticide per hectare on the 8.8 million hectares of cowpea grown in Africa, that is, spreading 2.2 million kilograms of insecticide into the African environment every year, not only onto the plants of course, but also into the soil, the air and the water.” This, of course, would result from a one-time spray. In some areas of West Africa, multiple sprays are used each season.

Cowpea is subject to many diseases and viruses but the losses they cause tend to be sporadic and local and are smaller, in general, than those caused by insect pests. The major foliar diseases are bacterial blight, bacterial pustule, *Ascochyta* blight, *Cercophora* leaf spot, brown and false rusts, and web blight. Stem diseases include *Pythium* stem rot, ashy stem blight and *Phytophthora* stem rot (Emechibe and Shoyinka, 1985). *Spaceloma* scab affects all above-ground parts of the plant. Eight viruses have been recorded on cowpea, most of which are insect borne. These include cowpea yellow mosaic comovirus, mottle virus, aphid-borne mosaic potyvirus, cucumber mosaic, cucumovirus, cowpea golden mosaic virus, mild mottle virus, and sunn-hemp mosaic tobamovirus (Thottappilly and Rossell, 1992). Root-knot and other nematodes are widespread and potentially injurious to cowpeas. Ongoing studies in West Africa are finding common occurrence in cowpea fields of root-knot *Meloidogyne* species as well as *Scutellonema cavenessi* (Boukar *et al.*, 2007). Two parasitic plants, *Striga gesnerioides* (Willd.) Vatke and *Alectra vogeli* (Benth.) cause nearly total crop losses in areas where the parasites are abundant (Atokple *et al.*, 1995; also see below).

1.5 Traditional Breeding

The goal of all cowpea breeding programs is to develop consumer-preferred varieties with high yield and resistance to biotic and abiotic constraints to production. Traditional plant breeding approaches to cowpea improvement have had many successes over the last 30 years. Much of the progress is due particularly to B.B. Singh, cowpea breeder at IITA Kano Station in Nigeria, and the large number of advanced breeding materials

and methods he and his students and colleagues produced over a quarter century of work. Bean/Cowpea CRSP scientists, particularly Tony Hall of the University of California at Riverside and his African students, have likewise made great contributions, as has Richard Fery of US Department of Agriculture (USDA)/Agriculture Research Service (ARS) working in the United States. Thanks largely to these and the work of other breeders, recent figures (2004) from the Food and Agriculture Organization (FAO) of the United Nations show a tremendous increase in the productivity of cowpea globally.

1.5.1 Breeding methods

1.5.1.1 Pedigree breeding

Three principal methods are used in breeding self-pollinated crops like cowpea: pedigree, mass selection, and single-seed descent. The pedigree method, often with slight modifications, is the one most frequently used. Segregating populations generated from crosses are selected at the F_2 and subsequent generations. Selections are based largely on the main character of interest, for example, resistance to the parasitic weed *Striga*. Detailed data on maturity, time to flower, growth habit, and grain and fodder yield are collected and the most promising single plants selected for advancement. Other traits of interest are selected for, as well, including seed color, seed texture, seed size, and leaf yield. The relative importance of these traits varies with the particular breeding program. For example, leaf yield is more important in eastern and southern Africa while West and Central African breeding projects lay more emphasis on grain and fodder yield.

When the pedigree breeding method is used, between 60 and 200 F_2 single plants are scored using a negative selection approach—those with undesirable traits, for example, black seeds, are discarded. Next, each of the selected F_2 plants is used to plant a progeny row. In the subsequent F_3 generation still more stringent selection criteria are used to reduce the population size further. Those F_3 families that breed true for the principal character are advanced to the F_4 generation. At F_4 evidence of segregation for the principal character is enough to prevent a family from

being advanced to the succeeding filial generation. From F_5 and F_6 onwards, attention is placed mostly on quantitative traits such as seed size, fodder yield, grain yield, and maturity. At this stage, all families must have been fixed for the principal character and within-family variation must be minimal—in other words family members need to be phenotypically uniform. At the F_6 generation, most of the families must have been fixed for not only the principal character of interest but also for most of the secondary characters. Subsequent evaluations of the F_6 through F_8 families are conducted mainly to assess yield and maturity performance. At each stage of selection, the breeder may save a portion of the seed of each family as insurance against crop failure.

The fully characterized families are then grouped on the basis of maturity group into early, medium, and late; or by seed color into brown, white, or other colors. Each group is then subjected to a preliminary yield trial (PYT). The trial is replicated at one or more locations. Locations are carefully selected to represent the typical production ecologies. The more promising entries, usually a maximum of 20, are pulled together from the various groups to form an advanced yield trial (AYT). The number of replications as well as test sites is greater for AYT compared to PYT. AYT can require 2 or 3 years depending on the breeder and the trait under consideration. The main aim of the AYT evaluation is to ensure rigorous evaluation of the genotypes under all possible stressful conditions. This helps to ensure that superior genotypes are selected. Eventually the AYT will have identified three or four most-promising lines; these are recommended for release. In some African programs national policy may require an additional on-farm evaluation by farmers to corroborate the breeder's claim about the superiority of the new lines over local commercial varieties. Some varieties developed using this approach are listed in Table 1.

The pedigree method of breeding requires meticulous records on the characteristics of each F_2 plant and its subsequent progenies through to the F_6 or F_8 generation. This makes the method cumbersome and time consuming. However, it has the advantage of allowing the breeder to compare the various families tracing their performance back to the antecedent F_2 plant. In addition, the genetic dynamics of several genes in the population

Table 1 Some cowpea varieties developed using the pedigree breeding method

Variety	Origin	Country of release
IT845-2246-4	IITA Ibadan ^(a)	Nigeria
IT89KD-245	IITA Ibadan	Nigeria
IAR-48	IAR2 Samaru ^(b)	Nigeria
IT90K-76	IITA Ibadan	Nigeria
IT89KD-374-57	IITA Ibadan	Nigeria
KVX-176B	INERA3, Ouagadougou ^(c)	Burkina Faso
IAR 355	IAR Samaru	Nigeria
IT90K-277-2	IAR Samaru	Nigeria

^(a)IITA, International Institute of Tropical Agriculture

^(b)IAR, Institute for Agricultural Research

^(c)INERA, Institut National Environmental Recherche Agricole

can be studied. Therefore, despite its drawbacks when used with self-pollinating crops like cowpea, the pedigree method is best for most situations.

1.5.1.2 Single-seed descent

To advance each selected F_2 plant derived from a cross or selfing program, a single representative seed from each plant is selected. This method has been adopted less widely in cowpea breeding. The few reported instances involve the development of pure lines from local landraces. Cowpea lines IT88DM-345, IAR-1696, and possibly IT85ID-985 are examples. A single seed is selected from each selfed plant from the various landrace collections. After the plants are evaluated for genetic purity, a single seed is then selected from each of the plants having the desired trait. This process is repeated until substantial phenotypic homogeneity is attained. Finally at the F_{6-8} level, seeds from the most promising strains are multiplied for further field evaluation, if the objective is to develop a pure line cultivar or if the line is to be included in a hybridization program to produce further improvement.

1.5.1.3 Backcross breeding

As with other crops, the backcross breeding method seeks to improve the genetic value of a locally adapted cultivar that has a few genetic defects such as susceptibility to diseases, low oil

or sugar content, etc. In practice, the hybrid between the adapted variety receiving the gene for further improvement—known as the recurrent parent—and the source of the gene of interest—the donor parent—are backcrossed again or several times, preferably as the male parent to the recurrent parent. With each backcrossing, in addition to acquiring the gene of interest, 50% of the genome of the recurrent parent is transferred into the backcross hybrid. For example, BC₁, BC₂, BC₃, and BC₄ are 50%, 75%, 87.5%, and 93.75% recurrent parent genome, respectively. Some of the varieties developed using this method include IT89KD-245, IT89KD-260, and IT90K-277-2. Seed size and general adaptation are the most common target traits for improvement using this approach.

1.5.1.4 Selection techniques

The overall success of a cowpea breeding program depends largely on the effectiveness of the selection tools used to identify desirable genotypes through their phenotypes. If the precision of the tools is low, improvement of the population for the trait will be small. Even when there is an effective tool for selection, the genetic variation in the genome must be sufficient to warrant exploitation—as is often not the case for major insect pests of cowpea. Barriers to genetic recombination between genotypes must also be surmounted to facilitate introgression of desirable genes into different backgrounds.

1.5.2 Major breeding objectives

1.5.2.1 Diseases

Breeders have employed different techniques to select disease-resistant genotypes. The development of disease-resistant cowpea cultivars is limited by the lack of screening techniques. These are not well developed for many diseases and hence, progress made from screening has been minimal. However, there are exceptions. To identify cowpea lines resistant to the *Cercospora* leaf spot disease, for example, Lane *et al.* (1994) inoculated cowpea accessions with spores of *Cercospora cruenta* in the greenhouse. Out of the 313 lines, 15 were

ranked as immune while 7 were judged resistant. Singh (1998) likewise relied on natural inocula to identify resistance to *Ascochyta* blight, *Septoria* leaf spot, and smut. He planted several hundred lines in fields with a history of the diseases—so-called hotspots. Lines failing to show any disease symptoms were tagged as resistant. Singh (1999) reported the development of improved lines with multiple resistances by planting rows of plants highly susceptible to a particular disease next to neighboring segregating lines. The susceptible line (spreader row) served as an inoculum bank, spreading the pathogens. This approach strongly aids selection for resistance. Based on reactions to three virulent strains of bacterial blight, Wydra and Singh (1998) used an artificial infection technique to identify three out of 90 varieties that were resistant to all the three blights. A similar approach was used by other researchers to identify resistant genotypes. The use of the spreader row is also the most efficient way of screening for resistance to *Sphaceloma* scab since artificial inoculation with an isolate of the pathogens fails to produce any symptoms of the disease even in susceptible genotypes (Mungo *et al.*, 1998). The success of developing disease-resistant cowpea varieties, therefore, lies largely with the availability of appropriate inocula together with optimum environmental conditions for symptom development.

As practical as field screening may seem, it is generally not as reliable as artificial inoculation. This is because natural inoculum abundance varies from season to season, making disease phenotyping subjective. However, field screening is the only available method of screening for resistance with diseases like *Ascochyta* blight, ashy stem blight, *Cercospora* leafspot, and smut diseases. Amusa and Okechukwu (1998) reported that planting of spreader rows 2 weeks before the test lines was more effective than simultaneous planting. Only 9 out of the 45 lines previously rated as resistant on the basis of simultaneous planting of spreader and test lines turned out to be actually resistant.

Although screening techniques are critical for the development of improved resistant genotypes, their usefulness is limited if a source of resistance is not present within the cowpea genome. Diseases, for which sources of resistance have been identified and used in breeding resistant cowpea varieties,

include brown blotch, rust, damping off, *Fusarium* wilt, and bacterial canker. Strain variation in disease pathogens makes artificial inoculation more critical for the development of resistant cultivars. This is because race-specific resistance will allow the development of varieties adapted to specific locations. To achieve a broader spectrum of adaptation, the resistance must encompass a series of strains of the pathogen. This is frequently the case for viral diseases. To identify sources of resistance as well as segregants possessing the genes in a breeding program, pure isolates of the viruses are usually sprayed on the test plants. In this way, Singh and Hughes (1999) identified sources of resistance to cowpea yellow mosaic virus (CYMV), black eye cowpea mosaic virus (BCMV), and aphid-borne mosaic virus (ABMV). Similarly, van Boxtel *et al.* (2000) reported multiple-strain resistant cowpea genotypes for BCMV and ABMV. Often, breeders use the disease reaction of cultivars with known resistance as the standard for strain-resistance breeding. van Boxtel *et al.* (2002) suggested that using the previously characterized cultivars IT86D-880, IT86D-1010, IT82D-889, IT90K-277-2, and TVU 201 and by introgressing all these parents in a breeding program, it is possible to develop a genotype with resistance to at least 13 different strains of the cowpea virus. However, the sustainability of the approach assumes that no new virus strains will develop or will develop slowly. To ensure sustained resistance, the breeder should continue to use the pathology tests to confirm resistance.

1.5.2.2 *Striga* and *Alectra*

The parasitic weeds *S. gesnerioides* and *Alectra vogelii* cause major yield loss in cowpea, sometimes reaching 100% in susceptible cultivars (Singh and Emechebe, 1990; Atokple *et al.*, 1995). Sources of resistance to *S. gesnerioides* have been identified in cultivar B301 (Singh and Emechebe, 1990) and IT82D-849 (Atokple *et al.*, 1995). Identification of resistant genotypes has been made easier thanks to a modified unispore culture technique like that used for disease pathogens. The soil in which the plants being evaluated are grown is first inoculated with the seed of the parasite; typically, about 800 seeds of *S. gesnerioides* per pot. Susceptible cowpea genotypes trigger *Striga* seed germination

and attachment to the host roots. Subsequently, the *Striga* plants emerge from the soil. Visual counts of emerged *Striga* plants in the pot alone are not sufficient to classify a cowpea plant as resistant or susceptible. The cowpea plant roots must be carefully washed to reveal any attachments, including immature haustoria. Fully resistant plants are free of *Striga* attachments while susceptible ones have one to several *Striga* attached. Although this method is laborious and time consuming, it is effective. Atokple *et al.* (1995) showed that in a pot containing two plants, one of them can support several *Striga* attachments, indicating susceptibility, while the other may be free of any attachments and resistant. However, in other pots both plants may be either susceptible or resistant. Another method, known as the *in vitro* technique, utilizes exudates from cowpea root cuttings and petri plates infested with *Striga* seeds. Root cuttings from susceptible cultivars elicit germination of the *Striga* seed while no seed germination is observed in resistant cultivars (Berner *et al.*, 1995). This method allows for the rapid screening, but it requires skill to use successfully. Lane *et al.* (1994), who screened and characterized *Striga* collections from West Africa, reported that there are 5 races—race 1 found in Burkina Faso, 2 in Mali, 3 in Nigeria and Niger, 4 in Benin, and 5 in Cameroon. Line B301 is resistant to all the races except 4, while resistance to race 4 is found in the variety IT81D-994. Varieties with multiple resistance to the various races have been developed using a combination of pot and field screening in so-called *Striga* hotspots (Singh, 2002).

The current extensive trade in cowpea grain in different West/Central African subregions means that cowpea cultivars with resistance to only one or two local races will not be effective because seeds of the parasite are also transported from one region to another along with the cowpea grain or fodder. The screening methods described earlier can be applied to the identification of resistance to all races of *Striga*.

Screening methods similar to those used to breed *Striga*-resistant cultivars have helped to identify *Alectra* resistance in B301 and IT81D-994. Genetic studies of the two genotypes revealed: (1) a pair of dominant resistance genes in B301, (2) a single dominant resistance gene in IT81D-994, and (3) that the two genes are nonallelic (Atokple *et al.*, 1995).

Table 2 List of selected cowpea varieties with resistance to *Striga gesnerioides* and *Alectra vogelii*

Genotype	Phenotype	
	Striga	Alectra
B 301 (1235) ^(a)	Resistant	Resistant
IT81D-994 (124) ^(b)	Resistant	Resistant
IT90K-76	Resistant	Resistant
IT90K-59	Resistant	Resistant
IT93K-693-2	Resistant	Resistant
IT97K-499-35	Resistant	Resistant
IAR-00-1009	Resistant	Resistant
IAR-01-1006	Resistant	Susceptible
IT97K-819-154	Resistant	Resistant

^(a) 1235 designates source of resistance to races 1, 2, 3, and 4

^(b) 124 designates source of resistance to races 1, 2, and 4

The pot culture technique has been effective as a breeding tool in the development of *Striga*- and *Alectra*-resistant cowpea varieties. However, employing it to screen for multiple strain resistance is not feasible because no single country has all the *Striga* strains. Furthermore, the different forms of *Striga* cannot be identified with precision using morphological markers. Table 2 shows examples of varieties with resistance to the *Striga* and *Alectra*.

1.5.2.3 Insect pests

Success in breeding cowpeas carrying resistance to insect pests depends primarily on the screening methods developed by entomologists. Progress has been made in rearing aphids, *Maruca* pod borer, cowpea bruchids, and to a lesser extent flower thrips. The insects thus made available are used to artificially infest cultivars and segregating populations to help to identify resistant plants.

Aphids can be maintained on highly susceptible cultivars grown in the screenhouse or glasshouse and then one or a few pairs of male and female adults transferred to test plants held in screening boxes. Susceptible plants support high colonization rates while the resistant lines remain free of any colony. The aphid-resistant genotypes TVU-3000 and TVU-801 were identified this way. This bioassay technique is now being used to identify resistance among segregating populations derived from crosses between aphid-resistant and -susceptible parents. Nkansah and Hodgson (1995) used this method to identify resistant

genotypes and transferred these genes into other backgrounds through backcrossing. Bata *et al.* (1987) screened segregating populations by planting them in a wooden box filled with topsoil. The box was covered with a screen to prevent the aphids from escaping. At intervals of about 10cm alternate rows of susceptible and resistant cultivars were planted. Resistant segregants did not support colony development, whereas the susceptible plants suffered high infestation and often were killed. Unfortunately, geographical variation in aphid strains makes the resistance in TVU-3000 ineffective in some locations, for example, in the United States and the Philippines though it is useful in Africa (Singh, 2002). Examples of aphid-resistant varieties include IT90K-76, IT90K-59-2, and IT84S-2246-4, all deriving their resistance from TVU-3000.

Screening of segregating cowpea populations for resistance to the cowpea bruchid (*C. maculatus*) involves rearing the adults on susceptible cowpea lines. Some 100–200 seeds of the test plant contained in a glass jar are infested with two pairs of adult bruchids. The test lasts 4–10 weeks. Resistance is indicated by the lack of holes on the grain while susceptibility is reflected in the number of emergence holes as well as number of adult weevils hatched. Landrace TVu 2027 has served as a source of resistance to develop bruchid-resistant cowpea cultivars. This resistance lasts only for about 90 days postinfestation, after which bruchid populations become high. Shade *et al.* (1999) reported that bruchid populations from some areas in Nigeria can overcome the resistance of TVu 2027, which establishes that there are strain variations in bruchids. The ultrasonic biomonitor device developed at Purdue University detects the presence of bruchid larvae feeding hidden within seeds by means of the ultrasonic signals the larvae generate as they feed (Shade *et al.*, 1990). This has the potential to be a useful tool for breeders because it could enable rapid and high-throughput screening of cowpea genotypes compared to the traditional glass jar methods. However, it should be noted that thus far no cowpea cultivar has been discovered that is immune to the bruchid beetle; in short, the current known resistance of TVu 2027 is only relative resistance.

Screening techniques for resistance against thrips have not been standardized. Breeders rely on natural infestation in the field to score genotypes.

Thus far, only a low level of resistance has been reported.

A well-documented screening technique for detecting resistance to the legume pod borer (*M. vitrata*) is available (Oghiakhe *et al.*, 1995). However, there is no known cultivar with more than weak resistance to this destructive insect. Interestingly, one relative of the cowpea, *V. vexillata*, is completely resistant to *M. vitrata*. Unfortunately strong genetic incompatibility prevents the cross from being made, and this renders *V. vexillata* of no value because it cannot be introgressed into cowpea by conventional crossing techniques (Barone and Ng, 1990). For other insect pests such as the lygus bug (Ehlers *et al.*, 2002), which belongs to the sucking bug complex (Ishiyaku and Amatobi, 2004), screening is solely based on natural field infestations where the breeder compares the performance of F₃ families or advanced breeding lines with and without pest protection (insecticide treatments). Some insect-resistant cultivars appear to give relatively high grain yields (Bata *et al.*, 1987). Even so, conclusions from such evaluations are difficult to make, especially during those seasons where the levels of natural pest infestation are low or moderate as this can lead to misleading results. Sources of resistance to the important sucking bugs, such as *Acanthomia* and *Aneplomis* species, do not appear to be present in the cowpea genome, making it impossible to develop resistant cultivars using a conventional breeding approach.

1.5.2.4 Physiological characters

Cowpea breeders give particular attention to the physiological characters of drought and heat tolerance, photoperiod sensitivity, maturity, and yield.

Cowpea is more drought tolerant than maize, sorghum, or even millet (Singh *et al.*, 1999a) and it displays significant genetic variation in response to moisture stress. Singh *et al.* (1999b) reported about a 15-weeks survival/development viability difference between the drought-susceptible cowpea line TVU-7778 and a drought-tolerant line TVU-11979. The evaluation was based on the stay-green trait.

The single dominant gene conferring drought tolerance was transferred into drought-susceptible

lines. Drought-resistant segregating lines were identified using the box screening technique. The test plants were grown together with the checks in a wooden box filled with a 1:1 mixture of sand and top soil. The plants were watered until the first trifoliate leaf emerged. Watering was then stopped and the time to permanent wilting as well as percent wilted plants among the test genotypes was determined to classify them as resistant or susceptible. This method is cheap and simple. However, it can be unreliable because of the lack of a record of soil moisture tension. Relying on time of withdrawal of water as an indicator of drought is problematic because the drought condition is related to the physical characteristics of the soil used. Nevertheless, drought-tolerant variety IT96D-604 was developed using this method and has been found to withstand relatively high soil moisture stress in the field.

After genetic variation for heat tolerance was identified in cowpea (e.g., Hall, 1992), efforts were directed to the introgression of heat tolerance into several different genetic backgrounds. Screening of segregating populations is done under high ambient temperatures for example, 43 and 24 °C as maximum and minimum temperatures, respectively. In Nigeria, the hot condition is characterized by temperatures of 24–27 °C minimum and 38–42 °C maximum. Heat-tolerant lines in the United States and Nigeria (Singh, 2002) were identified by planting in the field during the hot season. Tolerant lines will support full flowering and pod set while susceptible lines show high flower bud and flower abortion with very low or no pod set (Ehlers *et al.*, 2002; Singh, 2002).

Improvement of cowpea phenology for the weather of the production area has been essential for the development of varieties for an agroecology. Photoperiod sensitivity is the primary determinant of phenological adaptation of popular landraces. Photoperiod sensitive lines flower toward the end of the rains, thereby allowing for timely production of good seeds. Most past breeding efforts focused on the development of day-neutral cultivars. Breeders used the longest day length part of the season to screen for this trait. The longest day length in the cowpea growing belt of sub-Saharan Africa is only slightly longer than 13 h. As short as it may look relative to 16 h-long days of the temperate zones, the long day in Africa is effective in eliciting delayed flowering among sensitive

genotypes such as the landrace Kanannado, IT89KD-288, IAR-00-1074, IT89KD-245. Day-neutral varieties include IT84s-2246-4, IAR 48, IT97K-499-35, IT88DM-345, and IT97D-941-1. Putative day neutrals are characterized by early flowering, requiring less than 45 days (Ishiyaku, 1997). To screen segregating populations, the natural day length can be extended by the use of incandescent lamps.

Yield is an important trait in cowpea, whether for grain or of hay. Although yield is often measured directly by weighing the total grain (or hay), some breeders use other traits such as pods per plant, seeds per pod, plant height, number of branches per plant as an indirect measure of yield. In common with all crops, there is nothing more important than improving yield.

1.5.2.5 Quality traits

Nutrition-related traits, though are invisible to the consumer, are the most important and yet most difficult to measure in cowpea. Total crude protein in grain has high genetic variation, ranging from 14% to 28%. Screening segregating populations for this trait is based on F₃ seeds, which provide the information on the F₂ plant. Other quality traits include the microelement contents of the grain such as iron, zinc, copper, and molybdenum. Breeding programs seldom pay much attention to these traits. Recently, it has become fashionable to enhance the nutritional value of crops and investments are being made to develop biofortified varieties especially in the cereals. Grain size in cowpea is important as consumers pay a premium (Langyintuo *et al.*, 2003) for the desired seed size. Consumers in Nigeria, for example, prefer large-seeded (>20 g/100 seeds) varieties.

1.5.3 Challenges for conventional cowpea breeding

Conventional approaches to breeding cowpeas have materially increased the productivity of the crop globally. Varieties are available that yield more than 1 ton per hectare, even in the face of severe *Striga* or *Alectra* infestations, leaf spot diseases, or aphid, and nematode infestations. This success owes to resistance genes against these

constraints that exist in the cultivated cowpea genome and which were moved into different genetic backgrounds by breeders. Over the years, these improvements have resulted in more than a doubling of the average yield of the crop, from about 100 kg ha⁻¹ to about 350 or so kg ha⁻¹. However, even this still-modest level of productivity can only be guaranteed if one or two insecticide sprays are applied. This is because those resistance genes mentioned above only affect plant growth while a fully developed resistant cultivar needs a whole series of insect resistance genes to protect the reproductive organs so they can develop into mature pods with well-filled grain.

Unfortunately, there are no utilizable resistance genes for postflowering insect pests in the cowpea genome. It is true that resistance to some insects such as the legume pod borer, *M. vitrata*, exists in a distant relative of cowpea, *V. vexillata*, but interspecific genetic barriers prevent hybridization. Lack of genes in the cultivated species and high barriers to crossing between related species have limited the success of conventional breeding in solving the major cowpea production constraint—insects. What is true for *M. vitrata* is also true for the cowpea bruchid, and for pod-sucking bugs and thrips. Lack of resistance genes is a major bottleneck that limits the success of conventional cowpea breeding. The breeder must resort to modern biotechnological tools to find these genes outside the cowpea genome and transfer them into cowpea. Given the successes with other crops such as maize, tomatoes, sweet potato, and cotton, genetic transformation to introduce insect resistance is feasible for cowpea.

1.6 Limitations of Conventional Breeding and Rationale for Transgenic Breeding

Conventional breeding and screening have led to notable successes in improving cowpea for certain traits but these tools are only useful for genetically improving cowpea when the cowpea gene pool contains the desirable genes. This is frequently not the case. Further, complex polygenic traits are hard to breed for, as are traits for which there are no good bioassays or markers. As mentioned earlier, conventional breeding is limited or even practically

useless for resistance to many of the insect pests of cowpea, insects being the pre-eminent pre and postharvest pests of the crop because the cowpea gene pool is devoid of the necessary genes. Likewise, there is little prospect for genetic improvement of cowpea by wide crossing. Cowpea is extremely well isolated from other *Vigna* species that might provide sources of resistance genes. Many efforts have sought to create viable wide crosses between cowpea and its nearest relatives but the gulf has proven too wide.

Three constraints to cowpea production and utilization are currently targets for improvement through genetic transformation.

The first is the legume pod borer, *M. vitrata*, which by itself can cause severe, even devastating losses. *M. vitrata* belongs to the Pyralidae, the family to which the European corn borer (ECB) belongs. ECB, a major pest of maize in the eastern United States, can be controlled by means of maize hybrids genetically engineered to express the *cry1Ab* gene from *Bacillus thuringiensis* (often referred to as *Bt*). In the USA Corn Belt, about one-quarter of maize now carries the *cry1Ab* gene. The protein product of this gene has been shown to be extremely toxic to *M. vitrata* when fed in the diet ($LC_{50} = 0.03 \mu\text{g g}^{-1}$ diet; L.L. Murdock, W. Moar, and R.E. Shade, unpublished observations). Accordingly, genetic transformation of cowpea to express the *cry1Ab* protein has an excellent prospect of imparting *M. vitrata* resistance, a trait otherwise not available.

Another constraint not adequately addressable through conventional breeding is resistance to cowpea weevil. While it is true that there are cowpea cultivars derived from the landrace TVu2027 with moderate resistance to cowpea weevil, this resistance has already been incorporated into many cowpea varieties and has been widely disseminated, both in Africa and beyond. It now appears that there are populations of cowpea weevil that can overcome the existing resistance. If these resistant weevil populations expand, the TVu2027 trait will decline in usefulness to the point of being useless for protection against weevils. Numerous genes have the potential to confer resistance to the cowpea weevil if transferred into cowpea and expressed in the seed. The most advanced of these involves transferring into cowpea an α -amylase inhibitor (αAI) gene from common bean. In common bean that gene

through its protein product protects the seeds against cowpea weevil and certain other bruchids though not against the common bean weevil. When that gene was linked to a seed-specific promoter and transferred into garden pea using gene technology, the garden pea seeds, which are normally susceptible to cowpea weevil proved to be highly resistant (Shade *et al.*, 1994). By transferring the common bean α -amylase inhibitor into cowpea and expressing it in the seeds, it should be possible to introduce a new source of weevil resistance into cowpea. Some uncertainty hangs over this undertaking, however, because of the possibility that the αAI gene will not be expressed in the recipient plant exactly as it is in the donor parent. This has been observed with αAI expressed in garden peas. The αAI protein from garden peas had small mass difference from that of the protein from common bean, a difference probably due to a variation in the degree of post-translational modification in the recipient species. The possibility that this variant protein—which still inhibits insect α -amylase and blocks weevil growth and development—might cause toxicity or allergenicity in consumers of the transformed seed has to be addressed (Prescott *et al.*, 2005). Several approaches such as alteration of the secondary or tertiary structure of the αAI protein or modification of the primary amino acid sequence to remove or change glycosylation sites are available to address this issue (Lehrer and Bannon, 2005).

Cowpea grain contains modest but significant amounts of oligosaccharides, such as stachyose and raffinose. Some individuals, and especially small children, suffer discomfort, sometimes severe, when they ingest cowpeas. As a result, some adults do not eat cowpeas at all. Furthermore, many mothers will not use cowpeas—despite its high protein content—to prepare important weaning foods because of the ensuing discomfort when babies consume cowpea-based foods. Galactinol synthases are key factors in the biosynthesis of oligosaccharides. Efforts are now underway to characterize the galactinol synthase genes in cowpea with a view to eliminating one or more of them using RNA interference (RNAi) and thereby reducing the levels of oligosaccharides in the seeds.

RNAi refers to the interference resulting from the introduction of double-stranded (ds) RNA into

cells. It represents a gene regulation strategy based on sequence-specific targeting and degradation of RNA. This phenomenon is also known as RNA silencing, or quelling in fungi. In plants, it functions both as an antiviral defense mechanism employing viral encoded suppressors of silencing as well as a mechanism in plant gene regulation. RNAi participates in a whole complex network of cellular defense mechanisms and numerous silencing signaling pathways involved in gene regulation at the transcriptional, RNA stability, and translational levels (Waterhouse *et al.*, 1998; Dunoyer and Voinnet, 2005). RNAi is highly specific, requires dsRNA to be effective and is extremely potent requiring only a few molecules of the homologous dsRNA to effectively shut down the targeted homologous messenger RNA (mRNA).

The RNAi approach has been used in gene manipulation and biotechnological applications. To date the technique has been used to make healthier cooking oils, virus-resistant plants and improved pharmaceuticals, and holds immense promise in the manufacture of new drugs for the control of both animal and human diseases. It has proven to be highly effective in plant disease-resistance applications (Lindbo and Dougherty, 2005). The RNAi technique could, therefore, be applied as a novel strategy for viral resistance in cowpea to complement the already successful conventional breeding and other possibilities, such as coat protein-mediated and RNA-mediated resistance strategies.

RNAi techniques are currently being explored for use in altering the oligosaccharide levels. For example, work at the University of Zimbabwe has focused on elucidating the presence of galactinol synthase (*golS*) genes in cowpea, a key regulatory enzyme in the biosynthesis of raffinose family oligosaccharides (RFOs) (Saravitz *et al.*, 1987). This work is aimed at down-regulating the presence of RFOs that have been implicated as flatulence-causing factors in cowpea. The RFOs are α -galactosyl derivatives of sucrose and comprise the trisaccharide raffinose, the tetrasaccharide stachyose, and the pentasaccharide verbascose. While a total of seven homologs have been identified in *Arabidopsis*, work is underway to establish the number of homologs present in cowpea, their expression levels, and distribution patterns in order to determine the appropriate homolog for silencing (Taji *et al.*, 2002).

2. DEVELOPMENT OF TRANSGENIC COWPEAS

As mentioned earlier, cowpeas are a good source of protein and highly digestible energy but its yields remain critically low, largely because of insect pests. Cowpea germplasm contains little or no resistance to these major insect pests and a gene technology approach for adding insect-protection traits has been a high priority for many years (Ehlers and Hall, 1997).

The first reported transformation experiments with cowpeas were conducted by Garcia *et al.* (1986, 1987) and although kanamycin-resistant callus was obtained, no plants were regenerated. Later, Penza *et al.* (1991) and Muthukumar *et al.* (1996) used longitudinal mature embryo slices and mature de-embryonated cotyledons, respectively, as target tissues. Although Penza and colleagues could not demonstrate stable integration of the transgenes, Muthukumar *et al.* (1996) obtained transgenic plants after selection on hygromycin. However, transmission of the transgenes to the next generation could not be demonstrated. Similarly, Ikea *et al.* (2003), using the particle gun method for cowpea transformation, found that the transgenes were transmitted to only a small proportion of the progeny and that there was no evidence for stable integration of the transgenes. A very promising regeneration and transformation system was described by Kononowicz *et al.* (1997) and although not pursued at the time, it did form the basis of a system that is reproducible and that obeys Mendelian rules of inheritance (Popelka *et al.*, 2006). This is the first cowpea transformation system capable of producing transformants on a field scale. Critical features of this system include suitable explants from cotyledonary nodes or embryonic axes and a tissue culture regime without auxins in the early stages, but which includes the cytokinin, 6-benzylaminopurine (BAP), at low levels during shoot initiation.

2.1 Transformation Methodologies

Mature dry seeds are the preferred starting material although seeds harvested from immature pods at maximum fresh weight of seeds can also be used. Dry seeds are threshed by hand to avoid cracking of seed coats and thus reduce

contamination with microorganisms. The protocol published by Popelka *et al.* (2006) has undergone significant modification. An updated method follows.

Dry seeds or immature pods are submerged in 70% ethanol for 2 min, rinsed with sterile deionized water and then treated for 30 min in 20% commercial bleach (8.4 g l^{-1} sodium hypochlorite final concentration). Immature seeds are removed aseptically from pods while mature seeds are imbibed overnight. Two different explants are routinely used for multiple shoot production, i.e., the embryonic axis and the cotyledon itself (Figure 1a, b). From an initial comparison of 19 cultivars and lines, it is now clear that most lines of cowpea can be transformed, the only caveat being that different tissue culture conditions need to be optimized for each line.

The selectable marker genes, *bar* (Molvig *et al.*, 1997) or *nptII* (Mazodier *et al.*, 1985; Boevink *et al.*, 1995) can be used for transformation. The *Agrobacterium tumefaciens* strain AGL1 (Lazo *et al.*, 1991) is the preferred strain for cowpea transformation. *Agrobacterium* containing the T-DNA is cultured overnight at 28°C on a shaker at 180 rpm and the suspension is centrifuged at $8000 \times g$ for 10 min and resuspended in Medium 1 (MS-basic medium; Murashige and Skoog, 1962) diluted one in ten and containing 30 g l^{-1} sucrose, 20 mM 2-(N-morpholino)-ethanesulfonic acid (MES), adjusted to pH 5.6 prior to autoclaving, supplemented with filter-sterilized MS-vitamins, 100 mg l^{-1} myo-inositol, 1.7 mg l^{-1} BAP, 0.25 mg l^{-1} gibberellic acid 3 (GA3), 0.2 mM acetosyringone, 250 mg l^{-1} Na-thiosulphate, 150 mg l^{-1} dithiothreitol, and 0.4 g l^{-1} L-cysteine). The explants are submerged without shaking in the bacterial suspension for 1 h following wounding in the meristematic regions with a scalpel. The treated explants are then blotted on sterile filter paper and transferred to solidified Medium 2 (Medium 1 containing 0.8% agar). After 4 days of co-cultivation, explants (Figure 1c, d) are transferred to Medium 3 (full strength MS medium, supplemented with 100 mg l^{-1} myo-inositol, 150 mg l^{-1} timentin, 30 g l^{-1} sucrose, 3 mM MES, 1.7 mg l^{-1} BAP, 5 mg l^{-1} phosphinothricin (PPT) or $25\text{--}50 \text{ mg l}^{-1}$ geneticin or 150 mg l^{-1} kanamycin, 0.8 g l^{-1} agar and adjusted to pH 5.6) for shoot initiation. After 2 weeks the first shoots (Figure 1e, f) have been initiated and they are then

separated from the explant tissue. The cotyledon is removed from the “shooting” cotyledonary node region and the hypocotyl and root section of the embryonic axis are removed leaving the initiated shoot attached to 5 mm of hypocotyl tissue. Cultures are transferred to fresh Medium 3 every 2 weeks following removal of dead and dying tissue (see Figure 1g, h for shoot development after 6 weeks). After four to six such subcultures, the surviving green shoots are transferred to Medium 4 (Medium 3 without BAP but supplemented with 0.5 mg l^{-1} GA3, 50 mg l^{-1} asparagine, 0.1 mg l^{-1} 3-indoleacetic acid, 150 mg l^{-1} timentin, and either PPT (10 mg l^{-1}), geneticin (50 mg l^{-1}) or kanamycin (150 mg l^{-1}), for shoot elongation. The shoots are subcultured every 2 weeks until single shoots are more than 1 cm long. These larger shoots are transferred from petri dishes to culture jars (80 mm height) for further shoot growth under selection and eventual rooting.

The majority of the regenerated shoots can be rooted *in vitro* on Medium 4, but shoots that are slow to root can be directly grafted onto 10-day-old seedlings by removing the seedling's cotyledons and primary leaves and replacing them by the *in vitro* regenerated shoot with the aid of a silicon ring. Difficulties in rooting of cowpea shoots on hormone free medium are well known (Brar *et al.*, 1999; Machuka, 2000).

Grafted or directly rooted plants are transferred to soil and allowed to establish in a high humidity chamber for 14–21 days before transferring to the greenhouse where they are gradually acclimatized to ambient humidity.

Legumes are generally regarded as recalcitrant to genetic transformation (Popelka *et al.*, 2004). Several methods and meristematic tissues have been tried including somatic embryogenesis and organogenesis (Kononowicz *et al.*, 1997; Machuka, 2000). Higgins and co-workers have found that undifferentiated, apparently embryogenic callus has failed to regenerate viable embryos and plantlets under their conditions. They therefore opted for regeneration via organogenesis, which has been a successful platform for transformation protocols in other plants, including several legumes (Schroeder *et al.*, 1993; Kononowicz *et al.*, 1997; Molvig *et al.*, 1997; Olhoft and Somers, 2001; Saini *et al.*, 2003; Sarmah *et al.*, 2004). The cotyledonary node or embryonic axis appears to constitute the most

Figure 1 The embryonic axis and cotyledonary node used for cowpea transformation. Dry seeds are imbibed overnight and next day the embryonic axis (a) is removed from the cotyledon (b) with its nodal region exposed. Embryonic axis (c) and cotyledonary node (d) after 4 days of co-cultivation in tissue culture. Embryonic axis (e) and cotyledonary node (f) after 2 weeks under selection in tissue culture. Shoots developing from embryonic axis (g) and cotyledonary node (h) after 6 weeks under selection in tissue culture

Table 3 Protocol for cowpea transformation

Time	Activity	Medium	Details
Day 1	Mature seed sterilization and overnight imbibition	Water	20% commercial bleach for 45 min followed by thorough rinsing with sterile distilled water
Day 2	Explant preparation	-	(a) Longitudinally bisected embryonic axes with shoot and root apices removed, attached to cotyledons or (b) isolated embryonic axes
Day 2	Infection	Liquid	<i>Agrobacterium</i> strain AGL1 with <i>bar</i> or <i>nptII</i> genes, incubated with wounded cotyledonary nodes or embryonic axes
Days 2–6	Co-culture of <i>Agrobacterium</i> and cowpea explants	M1 Solid	4 days on thiol-containing solid medium
Day 6	Shoot initiation	M2 M3 (with selection)	Multiple shoot induction on BAP containing medium; begin suppression of <i>Agrobacterium</i> with timentin and start selection
Days 14–18 and 2 weekly	Remove initiated shoots from explants	M3 (with selection)	(a) Remove cotyledons at day 14 and embryonic axes 5mm below shoot apex at day 18 (b) Subculture on selective medium every 2 weeks from day 6 (c) Remove brown tissue parts at each subsequent subculture
Weeks 8–14 Weeks 14–17	Shoot elongation (a) Root initiation or grafting (b) Transfer to soil in greenhouse (c) Molecular analyses	M4 (with selection) M4 (with selection)	Selection of single healthy shoots (a) Root stocks of nontransgenic cowpea seedlings germinated for 10 days prior to grafting of putative transgenic shoots (b) Growth in high humidity chamber for up to 3 weeks prior to transfer to ambient conditions (c) Analyze expression of selectable marker and reporter genes and conduct PCR analysis
Week 20–32	Flowering and seed set Analysis of progeny		Self-pollination Expression of selectable marker and reporter genes, integration analysis by Southern blot and PCR

suitable explants for successful transformation experiments in legumes (Schroeder *et al.*, 1993; Pigeaire *et al.*, 1997; Olhoft and Somers, 2001; Popelka *et al.*, 2004).

To enhance gene transfer to cowpea, co-culture media is supplemented with thiol compounds, as described earlier for soybean (Olhoft and Somers, 2001; Olhoft *et al.*, 2003). The addition of L-cysteine, dithiothreitol, and sodium thiosulfate reduces browning of wounded tissue. Large numbers of cowpea explants can be processed in a simplified protocol (Table 3). In brief, the protocol consists of the following steps: (1) imbibition of sterilized mature seeds overnight in water, (2) explants are derived either by longitudinally bisecting embryonic axes with shoot and root apices removed but still attached to the cotyledon, or by isolating intact embryonic axes without

cotyledons, (3) infection with *Agrobacterium* strain AGL1 aided by local wounding in the meristematic regions, (4) co-culture on medium containing thiol compounds over 4 days at 25 °C in light, (5) shoot initiation and elongation on medium containing selective agents, (6) shoots are usually rooted *in vitro* or occasionally grafted onto nontransgenic seedlings and transferred to greenhouse conditions for flowering and seed setting, (7) polymerase chain reaction (PCR) or enzyme analysis of putative transgenic plants, and, (8) screening of next generation progeny by PCR.

The progeny of transgenic T₀ plants are normal in phenotype (Figure 2). The transgenes are transmitted to the progeny and homozygous T₂ plants, can be identified by screening their T₃ progeny for enzyme activity or by PCR (Popelka *et al.*, 2006).

Figure 2 Transgenic cowpeas in the greenhouse

Using this transformation system, it is now possible to produce 1–3 transgenic plants per 1000 explants, similar to other legume systems (Popelka *et al.*, 2004). Depending on the cultivar or line to be transformed, this protocol requires 5–8 months from explant preparation to harvested T₁ seeds. Enhancements to the level of transformation frequency may lead to a more efficient system (Chaudhury *et al.*, 2007).

2.2 Regulatory Measures—General Overview for *Bt*-Cowpea

Genetic transformation of cowpea has focused primarily on the development of *Bt*-cowpea, with other applications (traits) expected later. Accordingly, the following discussion will concentrate on *Bt*-cowpea only. Expectations are that it will be grown and consumed almost exclusively in Africa. Its developers have pledged to test and produce *Bt*-cowpea only in those African countries with functional regulatory systems. Most African countries are just now (2006–2007) in the process of developing the laws, regulations, guidelines, and institutional processes for safety assessment and testing of genetically modified (GM) crops. These are critical to the success of *Bt*-cowpea since lack of a transparent, science-based regulatory system is one of the major impediments to transfer of GM technology to developing countries (Traxler, 1999). For *Bt*-cowpea, as with other biotech crops, the regulatory dossier will need to encompass food, feed, and environmental safety. Successful commercialization will initially require regulated and contained production of *Bt*-cowpea seed in Australia, where the trans-

formation system was perfected (Popelka *et al.*, 2006). This will be followed by export from Australia and import into one or more West African countries where it will be assessed in confined field trials. Alternatively, contingencies for contained and/or confined evaluation in the United States are also being considered. Since Africa is the center of origin of cowpea the issue of potential gene flow to wild cowpea species will have to be assessed in the context of the overall risk assessment and approval process. Once regulatory approvals are attained, successful commercialization will result in release of *Bt*-cowpea into the farming environment. Because cowpea is widely traded across West African countries, the transboundary movement of *Bt*-cowpea seeds, vegetable matter, and processed products will also need to be addressed, since these African countries are signatories to the Cartagena Protocol on Biodiversity.

2.2.1 The Cartagena protocol on biodiversity and the biosafety protocol

The Cartagena Protocol on Biosafety (CPB) to the Convention on Biological Diversity (CBD) is an international instrument, ratified by more than 140 countries who are Parties to the CBD (CBD, 2005). The CPB also provides guidance regarding regulations, management, and risk control for the international trade of living modified organisms (LMOs). Key elements of the instrument are: (i) conservation and sustainable use of biodiversity, (ii) sharing of information (e.g., the basis for regulatory approvals), and (iii) based on an “adequate” level of protection. Many cowpea-producing African countries are signatories to the CPB, which went into effect in September 2003 (<http://www.biodiv.org/biosafety/signinglist.asp?sts=rtf&ord=dt>). The CPB requires every signatory to have a functioning regulatory framework in place to implement the CPB. Of particular importance is Annex III of the CPB that addresses environmental risk assessment of LMOs such as GM crops. A key benchmark for regulatory progress of *Bt*-cowpea will be the ability to test material in the field under confined field trials and then, once approved, under commercial field production. The CPB outlines procedures for the intentional release of

GM crops into the environment by the country of import. To date, the process involves import of the test material following the regulatory regulations and guidelines of the specific importing country.

For *Bt*-cowpea, the issue of transboundary movement of LMOs used for Food, Feed, or Processing (LMO-FFP) will have to be addressed because cowpea is routinely traded across West Africa. The CPB contains simplified procedures for the safe handling and transport of LMO-FFPs. In particular, Article 11.4 states that a country can use its domestic regulatory framework to address LMO-FFP as long as it is consistent with the objectives of the CPB. Article 11.6 addresses developing countries with economies in transition and states that for LMO-FFPs countries need to provide a risk assessment consistent with Annex III, a decision within 270 days and communication through the biosafety clearing house. These provisions will be useful to African countries that have not finalized their regulatory frameworks and guidelines for GM crop production in country, but which still need to import cowpea food and feed from a neighboring African country. This is particularly important in Africa where many countries import commodity grain each year as part of humanitarian relief efforts.

2.2.2 Annex III of the biosafety protocol—environmental risk assessment

Under Annex III of the CPB the objective of risk assessment is to identify and evaluate the potential adverse effects of LMOs on the conservation and sustainable use of biological diversity taking into account risks to human health. Annex III provides a set of principles, general methodologies, and points to consider in conducting environmental risk assessments. These principles are consistent with virtually every legitimate functional regulatory system described in this chapter. Most of the major GM-producing countries are not signatories to the CPB, however, whatever the source, the guidelines follow many of the same principles, the most important of which is that they be science based (Hill, 2005). An important difference is the use by the CPB of the poorly defined precautionary approach, or principle as it is sometimes called, which has been used by some as a mechanism to deny

import approvals (Hathcock, 2000; Conko, 2003). International treaties and other obligations are also part of the decision-making process. Recent activity at the World Trade Organization between the EU and several GM crop-producing countries illustrates this dynamics.

Some of the general principles of the Annex include:

1. The risk assessment should be science based, transparent, and make use of expert opinion and guidelines developed by relevant international organizations.
2. Lack of scientific knowledge or scientific consensus should not necessarily be interpreted as indicating a particular level of risk, an absence of risk, or an acceptable risk.
3. Risks associated with LMOs or LMO-FFPs should be considered in the context of the risks posed by the nonmodified recipients or parental organisms.
4. Risk assessment should be carried out on a case-by-case basis, i.e., *it should not be prescriptive*. The intended use and likely receiving environment are key determinants.

The methodological framework for the risk assessment involves the following steps:

1. An identification of any novel genotypic and phenotypic characteristics of the LMO.
2. A determination of the likelihood of adverse effects taking into account levels of exposure.
3. An evaluation of the consequences should adverse effects occur.
4. An overall risk estimate based on the likelihood and consequences of the adverse effects occurring.
5. A recommendation as to whether the risks are acceptable or manageable, including strategies for risk management or monitoring.
6. The risk assessment takes into account all of the relevant technical and scientific details as outlined earlier for the Food Safety Assessment. In addition, it also contains information regarding:
 - a. The biological characteristics of the recipient or parental organism, including taxonomy, centers of origin, and genetic diversity and a description of the habitat where the organisms may persist or proliferate.

- b. The methods of detection and identification and their specificity, sensitivity, and reliability.
- c. Information relating to the intended use of the LMOs, and
- d. Information on the location, geographical, climatic and ecological characteristics, including information on biological diversity and centers of origin of the receiving environment.

2.2.3 The regulatory process with the US regulatory system as a model

The US regulatory approval process for a GM crop illustrates the key features needed to attain a regulatory approval of a GM crop in the United States (Chassy, 2002). The US model is not necessarily the best model, but it has been used successfully to evaluate and approve nearly every commercialized GM-crop product released to date. Accordingly, institutions in Africa will have to develop or acquire the capacity to similarly scientifically evaluate the food, feed and environmental safety of *Bt*-cowpea.

The US regulatory process has nine stages or steps, as follows:

1. Biosafety Committee—National Institutes of Health Biosafety Guidelines.
2. USDA greenhouse standards and inspections.
3. USDA field trial authorization.
4. USDA authorization of transport for field trials.
5. USDA determination of nonregulated status.
6. Environmental Protection Agency (EPA) experimental use permit (EUP) approval.
7. EPA determination of food tolerance or tolerance exemption.
8. EPA environmental assessment and product registration.
9. FDA food and feed review process.

The process begins with the initial laboratory experiments performed under an institution's biosafety committee following US National Institutes of Health (US NIH) guidelines. Transgenic plants then enter an interagency coordinated framework for the regulation of biotechnology products. The three lead US Regulatory agencies are: the US Department of Agriculture (USDA),

the Food and Drug Administration (FDA), and the Environmental Protection Agency (EPA) (CAST, 2001; USDA, 2006).

The FDA is the US federal authority that determines food and feed safety, importation, and proper labeling of foods (CAST, 2001; USDA, 2006). In the consultative process the FDA reviews safety data supplied by the GM crop's developer to determine if there are, for example, any food safety issues with allergenicity or altered nutrient levels. While the US FDA uses a consultative process other countries, for example, the EU, Canada, and Japan, require formal food approvals. After commercialization, the FDA has the authority to suspend or restrict sales if a safety issue is found.

The USDA Animal and Plant Health Inspection Service (APHIS) is charged with protecting the US agricultural environment from pests, diseases, and weeds (USDA, 2006). The role of APHIS centers largely on assessing whether a new plant variety can harm native plants or other organisms or whether a GM plant variety has the potential to become a pest (i.e., a weed). The potential for gene flow from a new GM crop variety and effects on nontarget organisms (NTO) are special concerns.

The US EPA regulates the sale, distribution, use, and testing of GM plant varieties modified to express pesticides such as *Bt* toxins and the herbicides applied to GM herbicide-tolerant crops (USDA, 2006). It also sets tolerance limits in food and feed. Key activities include the issuance of EUPs for field testing and conduct of the environmental risk assessment and the endangered species risk assessment. The US EPA is also responsible for the insect resistance management plan (IRM) requirements, which are postcommercial conditions of registration.

Three crucial safety assessments will have to be conducted for *Bt*-cowpea to receive the regulatory approvals needed for registration and commercialization. These deal with food, feed, and environmental safety.

2.3 Safety Assessments for *Bt*-Cowpea

2.3.1 Food safety assessment

The Codex Alimentarius Guideline CAC/GL 45-2003 produced by the FAO/WHO Food

Standards Program is used by regulatory bodies worldwide as a guideline for food safety assessment (Codex Alimentarius, 2003; Chassy *et al.*, 2004). The guideline is based on the concept of substantial equivalence, which says that safety is best assessed by comparing defined differences between a transformed plant and its most similar untransformed line (EuropaBio, 2003). The approach relies heavily on compositional analysis (Chassy, 2002; Chassy *et al.*, 2004; ILSI, 2006). Below is a summary of the GL 45-2003 guideline and a description of some of the key general information that will need to be addressed for *Bt*-cowpea. Needed are:

- A. A description of the recombinant-DNA-cowpea plant. This will cover the crop, the transformation event, and the type and purpose of the genetic modification.
- B. A genotypic, phenotypic, and taxonomic description of cowpea and its use as food and feed. Needed also is a breeding history and identification of any traits, for example, allergens that may have an adverse effect on humans and animals. The history of cowpea as a food will also be covered, addressing the fact that virtually all parts of a cowpea plant are consumed including the seeds, pods, and leaves. In addition, these are consumed at both the immature and mature stages.
- C. A taxonomic and biochemical description of the donor organism, addressing especially any naturally occurring toxins, allergens, or pathogenicity.
- D. A description of the genetic modification(s) including the transformation method, the DNA and genetic elements, markers or other regulatory elements of the gene of interest, their size, orientation, and function.
- E. A complete molecular and biochemical characterization of the genetic modification(s) including the number of insertion sites, copy number, and sequence information flanking the insert as well as any open reading frames resulting from the insertion. Information on tissue-specific expression levels will be included. It should be noted that, to date, no direct correlation has ever been made between the molecular (genotypic) analysis and safety. Accordingly, the emphasis of the safety assessment is on the phenotypic analysis.

- F. A safety assessment to address toxicity and allergenicity (Goodman *et al.*, 2005). A compositional analysis of key biochemical components and metabolites will be provided.

2.3.2 Feed safety assessment

Because cowpea leaves are fed to animals, a feed safety assessment will be needed. The approach to assessing feeds varies widely by country. In the United States, feed is treated legislatively in the same way as food while in other countries such as Canada there is feed-specific legislation (OECD, 2003). In general, many of the issues associated with the safety assessment for food also apply to feed since both humans and animals frequently eat the same materials. For example, the *Bt*-cowpea safety assessment of food or feed will both provide a full characterization of the introduced genetic elements, information on any substances that may result from the modification, and whether any unintended effects occurred as a result of the transformation (OECD, 2003).

As is the case for the food safety assessment, the basis for the feed safety assessment is substantial equivalence (Kleter *et al.*, 2001; Chassy *et al.*, 2004; Berton and Marsan, 2005). However, animal feed, including cowpea used as feed, frequently differs from human food in terms of the form (e.g., silage), the degree of processing (raw vs. uncooked), quantity consumed, and specific tissues fed to livestock. Most importantly, consideration will be given to the quality and nutritive value of the *Bt*-cowpea as used in feed for livestock and for the safety of consumers of animal products derived from the livestock (OECD, 2003).

2.3.3 Environmental risk assessment

Environmental risk assessment (ERA) is an evaluation process that determines the likelihood of adverse effects—as well as the uncertainty associated with that determination—occurring to the environment after exposure to one or more stressors (e.g., a *Bt* toxin) (US EPA, 1998; Wilkinson *et al.*, 2003; EFSA, 2004). In some cases, the ERA may include risks to both humans and the environment, and may address direct, indirect, immediate, and delayed effects (EC, 2001/18/EC).

A risk assessment comprises problem formulation, hazard identification, hazard characterization, exposure assessment, and risk characterization (US EPA, 1998; EFSA, 2004). Because no technology is without risk, risk management and mitigation must also be considered.

A GM crop destined for commercial release requires an extensive ERA be conducted in the country(ies) of production (EC, 2002; EFSA, 2004; Mendelsohn *et al.*, 2004). All currently commercialized products have been assessed for environmental risks based largely on the US EPA's ecological risk assessment guidelines (US EPA, 1998; Mendelsohn *et al.*, 2004; Pew, 2004). Some countries, for example, Australia, Canada, and the European Union, have their own guidelines, but historically much of the data were built off the USA dossier (OECD, 1993; CFIA, 1994; US 7 CFR §340, 1998; EU, 2001; EC, 2002; EuropaBio, 2003; EFSA, 2004; OGTR, 2006; CPB, 2007). Detailed summaries of the evaluation process are provided in the US EPA Biopesticides Registration Action Documents (US EPA, 2008).

Because of the intended pesticidal nature of *Bt*-cowpea, there will need to be an extensive assessment of its potential effects on NTO. The best guidance will be to use the science-based and -tested surrogate species, tiered approach, used for assessing all current commercially approved biotech products (EuropaBio, 2004; Garcia-Alonso, 2006; US EPA, 2007; Romeis *et al.*, 2008). In the United States, regulatory guidelines for NTO risk assessment of insect-protected crops were developed by the US EPA and refined through Science Advisory Panels (SAP) (US EPA, 1996, 1998, 2001a–c, 2008). This approach will be based on potential exposure scenarios and characterization of hazard (toxicity). The selection of the test organisms and test materials will be based on the characteristics of the trait, i.e., Cry1Ab, and the expression pattern in the plant. Although northeastern Africa appears to be the center of origin of cowpea, an assessment of the potential for gene flow (often used synonymously with the term “outcrossing” or “cross-pollination”) will have to be assessed for cowpea grown in West Africa. While cowpea is a closed-pollinated crop and it may be able to outcross naturally, albeit at very low rates and influenced in part by flowering times, the proximity of alternative pollen sources as well as

temperature and humidity, available pollinators, and field architecture. Given all of these factors, a thorough assessment of the potential for gene flow will be necessary.

2.4 Safety Evaluation of *Bt*-Cowpea in Africa

2.4.1 Production of *Bt*-cowpea in Australia—regulatory issues

Bt-cowpea was created with a *cry1Ab* gene construct in the laboratory of T.J.V. Higgins, CSIRO, Canberra, Australia. The *Bt*-cowpea product concept is control of the legume pod borer. Since the borer occurs in Australia, CSIRO will also be able to conduct the initial line selections in Australia. Accordingly, the first set of regulations to address *Bt*-cowpea will be those of the Commonwealth of Australia. Activities (“dealings”) associated with GM Crops are regulated in Australia under the Gene Technology Act of, 2000 (Linacre *et al.*, 2006; OGTR, 2007). Under the terms of the Act, several government agencies are responsible for regulating genetically modified organisms (GMOs). These include the Office of the Gene Technology Regulator (OGTR), which regulates the use of GMOs and the Food Standards Australia New Zealand (FSANZ), which regulates food produced through the use of biotechnology. The point person in the OGTR is the Gene Technology Regulator (GTR), whose responsibilities and decision-making authority address GMOs in research, manufacturing, production, experimental trials, commercial release, and importation. Every dealing with a GMO must be licensed by the Regulator, unless the dealing is (i) exempt, (ii) a notifiable low risk dealing (NLRD), or (iii) on the Register of GMOs. The *Bt*-cowpea being developed in Australia is classified as a NLRD because the dealing is considered low risk since it will proceed only under containment in the laboratory and glasshouse with no intentional release into the Australian environment. This level of authorization requires Institutional Biosafety Committee (IBC) oversight and notification of the Regulator. Because *Bt*-cowpea is being developed for use in Africa and will not be released into the Australian environment or sold within Australia,

a food and feed safety assessment for submission to FSANZ will not be necessary.

2.4.2 Confined field trials in Africa

Once produced in Australia, cowpea seed will be shipped to one or more West African countries for use in confined field trials (CFT). CFT serve two purposes (Linacre and Cohen, 2006). First, they allow plant breeders to collect and assess important agronomic data. Second, data are generated in the CFT to assess human, animal, and environmental safety and provide a key element in the risk assessment. Countries regulate CFT through an application process that requires biological information outlined in the discussion of the food, feed, and ERAs, information on the trial site(s) itself, as well as confinement measures and contingency plans (OECD, 1992; CropLife, 2005; Linacre and Cohen, 2006). The ability of the plant to escape confinement and persist in the environment is a key issue to be addressed. To this end, guidelines will address spatial separation from other crops and plants, and control of reproductive structures and harvesting (OECD, 1992). As has been discussed for CFT in East Africa (Linacre and Cohen, 2006), regional harmonization of applications and guidelines are likely possible for West African countries.

2.4.3 The Burkina Faso regulatory model

As mentioned earlier, many African countries are in the process of formulating their biosafety laws, regulations, and guidelines. This situation with regard to regulatory status is changing rapidly. However, as of early 2007, only one major cowpea-producing African country, Burkina Faso, has developed a fully functional regulatory system and was in fact testing a GM crop under CFT. Given its development, Burkina Faso may illustrate what the regulatory climate might look like in other cowpea-producing African countries. Burkina Faso Law No. 005-2006/AN establishes the regulatory conditions for using GMOs and their derivative products (Burkina Faso, 2006). This comprehensive law addresses risk assessment, risk management, and information and control mechanisms involved in the use, dissemination and transboundary movement of GMOs and products

derived from them. It addresses GMOs that could have harmful effects on the environment, human, and animal health, or which are capable of affecting the sustainable conservation and use of biodiversity. This Law also addresses the development, experimentation (including confined and field tests), production, diffusion, storage, and destruction of GMO products and their derivatives.

The regulatory structure created in Burkina Faso comprises a supervisory agency and three consultative bodies. The National Biosafety Agency (ANB) is the overall national authority on the issue of biosecurity. The National Biosafety Observatory (ONB) is a consultative body responsible for biosafety, surveillance, and education. The National Scientific Committee on Biosafety (CSNB) is a consultative body responsible for biosecurity. The Internal Scientific Committee on Biosafety (CSIB) is the expert body responsible for biosafety scientific evaluation. The process used in Burkina Faso comprises several steps including:

- The import of GM products or products derived from them requires written authorization from the ANB.
- The ANB may ask for additional information before delivering a decision.
- To obtain authorization for the import, confined use, dissemination, and marketing of a GMO or derivative product the applicant must conduct a risk assessment to determine risks according to a timeline set by the ANB.
- The ANB issues an authorization after establishing that the import, confined use, dissemination, and marketing of a GMO or a derivative product can benefit the country without causing any risk to human and animal health, biodiversity, or the environment, and contribute to sustainable development and cause no harm to the socioeconomics of Burkina Faso and comply with ethical rules.
- The applicant must provide the ANB with evidence that it is capable of fulfilling its obligations, as specified in No. 005-2006/AN.
- Authorization can be revoked or suspended if conditions of the registration are not met or if the ANB obtains information that the GMO or derivative product presents risk to human and animal health, biodiversity, or the environment.

2.4.4 Regulatory status of cowpea-producing African countries

The following is a summary of the current state of regulation for GM crops in cowpea-producing African countries as of April 2007 (cf. http://www.absf africa.org/php/about_absf.htm).

Benin has signed, ratified, and put the CPB in force. Benin was involved in the UNEP-GEF Biosafety Framework project but not in the implementation project. At present, Benin has no biotechnology policy, biosafety guidelines, or regulation (ABSF, 2008).

Burkina Faso has signed, ratified, and entered into force the CPB. Burkina Faso was involved in the UNEP-GEF Biosafety Framework project but was not an implementation project. However, Burkina has passed and signed into law its national biosafety legislation. Implementation by laws have been drafted and scheduled for approval by the Council of Ministers by the first quarter of 2007.

Cameroon has signed, ratified, and entered into force the CPB. Cameroon participated in the UNEP-GEF Biosafety pilot program and the Biosafety Implementation Project. Cameroon has drafted biosafety guidelines. National Biosafety legislation is in draft form (ABSF, 2008).

Chad has signed the CPB but has not ratified it. Chad was also involved in the Biosafety Development Project. Chad has not enacted any Biosafety legislation (ABSF, 2008).

Côte d'Ivoire has not signed the CPB. Côte d'Ivoire was involved in the Biosafety Development Project. Côte d'Ivoire has not enacted any Biosafety legislation.

Ghana has ratified and entered into force the CPB. Ghana participated in the Biosafety Development Project. Currently Ghana is developing its biosafety policy and guidelines (ABSF, 2008).

Mali has signed, ratified, and entered into force the CPB. Mali participated in the Biosafety Development Project. Mali does not currently have any biosafety policy in place (ABSF, 2008). A National Biosafety Framework has been prepared but has not been reviewed by the Government and the National Assembly (CPB Interim Report 9 September 2005).

Mauritania ratified and entered into force the CPB. Mauritania participated in the Biosafety Pilot Phase. Mauritania does not currently have

any biosafety policy, guidelines, or legislation in place (ABSF, 2007).

Niger has signed, ratified, and entered into force the CPB. Niger participated in the Biosafety Development Project. Niger does not currently have any biosafety policy, guidelines, or legislation in place (ABSF, 2007).

Nigeria has signed, ratified, and entered into force the CPB. Nigeria participated in the Biosafety Development Project. Nigeria currently has national biosafety guidelines and a national biosafety committee in place (ABSF, 2007).

Senegal has signed, ratified, and entered into force the CPB. Senegal participated in the Biosafety Development Project. Senegal is finalizing its biosafety regulations and biotechnology policy (ABSF, 2007).

Togo has signed, ratified, and entered into force the CPB. Togo participated in the Biosafety Development Project.

3. FUTURE ROAD MAP

Biotechnology-based improvements of cowpea are likely to have major impacts on cowpea productivity in sub-Saharan Africa, and on incomes and welfare of cowpea producers, consumers, and other end users involved in the value chain. Cowpea yield potential is as high as 2500 kg ha⁻¹, yet current yields are far less—in the 350–700 kg ha⁻¹ range. The present low yields are due to pests, diseases, poor access to improved seeds and field, and storage pest control equipment and pesticides, as well as limited market outlets. Insect pests remain the most important limitation to cowpea production and post harvest storage (see below).

Plant breeding research at IITA, by the Bean/Cowpea CRSP (Collaborative Research Support Program) and by national research systems has developed high-yielding dual-purpose (fodder and grain) cowpea types that (i) have some tolerance to biotic and drought stresses, and (ii) high nitrogen and phosphorus use efficiency. Use of these materials (e.g., IT90K-277-2, IT97K-499-35, IT98K-131-2) in combination with improved and integrated crop management practices has the potential to increase cowpea productivity and incomes by 300% in West Africa (Singh *et al.*, 1997). These technologies are now available for

wider dissemination (James *et al.*, 2003), but additional research is needed to develop and adapt other options to specific agroecological and socioeconomic conditions.

Higher productivity of cowpea and more effective pest control with minimal concomitant health and environmental costs requires more than conventional breeding and frequent sprays of highly toxic pesticides. Breeding and development of cowpea varieties with natural resistance to the major insect pests has limited prospects. Extensive screening of cowpea germplasm over many years to find natural resistance to legume pod borer (*M. vitrata*), thrips, pod-sucking bugs, and cowpea weevil has revealed that the cowpea gene pool is poor or even devoid of useful genes for resistance to some of these pests. This means that certain of these constraints to cowpea productivity simply cannot be relieved via conventional breeding and screening alone. A needed adjunct is to use the tools of biotechnology to bring new genes into the cowpea gene pool (genetic transformation) and to use the tools of marker-assisted selection to more efficiently assemble multiple useful genes in single cowpea cultivars. Genetic modification to introduce vital genes can be used to address specific crop productivity problems that cannot otherwise be easily solved. One step in the process is the identification and cloning of genes that eventually could be used to transform cowpea (Fatokun, 2002; Murdock, 2002).

Using the tools of biotechnology the development of genetically improved cowpea lines with resistance to major pests would contribute significantly to (1) increased production and incomes, (2) improved nutrition, (3) lower prices and a greater supply of cowpea for consumers in the growing cities of Africa, and (4) improved soils and soil stability. Sithole-Niang *et al.* (2001) reported that small-holder farmers in South Africa benefit proportionately more from *Bt* cotton than larger-scale commercial farmers.

Biotechnology applied to cowpea offers a cost-effective solution and a substantial opportunity for crop improvement. The legume pod borer (*M. vitrata*), which belongs to the family Pyralidae, is highly sensitive to certain *Bt* crystal toxins. Work by T.J. Higgins and colleagues at CSIRO (see above) has led to the development of a reliable transformation system for cowpea. Specific *Bt* proteins (*cry1Ab* and others) active against

M. vitrata have been identified at Purdue University. This work has set the stage for the development of a *Bt*-cowpea for deployment in West Africa for use in controlling *M. vitrata*.

In sub-Saharan Africa, the controversy surrounding biotechnology appears to be related to the uncertainty about the risks or safety associated with GMOs. Many applications of biotechnology are not known to urban or rural consumers, yet could have tremendous impact on agricultural productivity. *Bt*-cowpea or other pest-resistant genetic improvements create the hope for a significant reduction in crop losses, lower pesticide residues, and improved food security. Like any other innovation, the products of biotechnologically improved cowpeas will be adopted if they provide concrete benefits for farmers and are not rejected by consumers. Langyintuo and Lowenberg-DeBoer (2003) predicted substantial benefits from *Bt*-cowpea for producers in Sahelian regions and for consumers everywhere in West Africa based on a regional trade model. Similar results have been described by Gbegbelegbe *et al.* (2006). However, Gbegbelegbe *et al.* (2006) have also pointed out that there are consumer concerns about *Bt*-cowpea in Nigeria.

Seed systems play a key role in the introduction and wide diffusion of GM crops worldwide and in resistance management plans necessary for the long-term sustainability of the genetic improvement. Unfortunately, seed production systems in West Africa are weak. Lambert *et al.* (2004) reported that seed producers in Senegal, Ghana, and Niger are interested in the idea of *Bt*-cowpea, but are also leery of a consumer backlash and of the responsibilities of resistance management.

3.1 Expected Products

There are several value-added genetic improvements of cowpea currently under development. The first GM cowpea will likely carry only a single *Bt*-gene, but this will likely be replaced quickly with a two-*Bt*-gene cowpea. Pyramided *Bt*-resistance genes whose protein products target different sites in the insect have both increased killing power as well as increased durability, i.e., are less likely to evoke the emergence of insect biotypes that overcome the resistance and render it useless. An

example of a pyramided GM cultivar is the newly released Bollgard II™ cotton that expresses two *Bt* genes with different sites of action in the insect (Greenplate *et al.*, 2003).

A new source of resistance to cowpea weevil is badly needed, and it will be possible to develop a bruchid-resistant cowpea that expresses the α -amylase inhibitor-1 gene from common bean. However, as has been observed when this gene is expressed in field pea seeds (*Pisum sativum*) (Prescott *et al.*, 2005), the protein product is slightly different from that produced in the common bean—due to a difference in post-translational modification. This difference raises questions about potential immunogenicity and even allergenicity as well as toxicity of the aberrant protein. As mentioned earlier, there are options available to obviate this concern but these issues will have to be resolved before serious consideration can be given to deploying an α -amylase inhibitor cowpea.

Other GM cowpeas are at earlier stages of development. These include those with reduced levels of oligosaccharides and thus improved consumer acceptance. Lowered oligosaccharides might open the way for cowpea to be used as the base for infant weaning foods.

Other genetic improvements not easily attainable by conventional breeding lie farther in the future. For example, several insect pests of cowpea, particularly thrips and the complex of pod-sucking bugs, cannot be controlled through plant resistance introduced through conventional breeding. Unfortunately, little or no effort has been expended to discover genes for resistance to these pests. As is the case with the *cryIAb* gene used for the development of *Bt*-cowpea, the genes are likely to come from an industrial laboratory. Until the needed bioassays are developed and applied to discover effective genes, resistance to these additional pests will remain out of reach.

3.2 Risks and Concerns

African Agricultural Technology Foundation (AATF) recently commissioned an assessment of the likely impact of deploying a high quality insect-resistant *Bt*-cowpea cultivar in West Africa; the study was carried out in 2006 by IITA and Purdue University (IITA and Purdue University, 2006)

scientists in major cowpea growing countries of Benin, Niger, Nigeria, Burkina Faso, and Mali. Its aims were to assess producer and consumer preferences, acceptability, willingness-to-pay, and adaptability of a GM cowpea to local conditions in West Africa. The preliminary results indicate that: (1) Information exchange and awareness are important for the adoption and region-wide diffusion of *Bt*-cowpea, (2) cowpea growers prefer *Bt* to conventional cowpea seeds in the sense that they would be willing to pay a higher price for *Bt*-cowpea seeds, (3) given the potential of reducing health hazards by lowering the use of toxic synthetic pesticides, both farmers and consumers would be willing to pay a premium price for *Bt*-cowpea as an alternative to harmful cotton pesticides. The opportunity costs of using cotton insecticides include the economic losses encountered by the farm household when a family member is sick due to the misuse of chemical insecticides, (4) urban consumers in regional markets believe that *Bt*-cowpea may be safer than conventional cowpea treated with chemicals, (5) *Bt*-cowpea will raise incomes substantially at the farm, household, community, and regional levels.

3.2.1 Ex ante impact assessment of *Bt*-cowpea

Economic analyses have been carried out in a few countries to estimate the impact of *Bt*-cowpea. They suggest that *Bt*-cowpea would provide an aggregate expected gross benefit (for rural and urban consumers collectively) estimated at US\$ 1.2 billion per year in Benin, 3.1 billion in Niger, and 8.4 billion in Nigeria. These estimates are at the high end as they are based on the probably false assumption that the seed costs for *Bt*- and conventional cowpea are equal. The unit cost of supplying *Bt*-cowpea seed may be substantially higher than for conventional cowpea. Even so, the benefits for resource-poor farmers and low-income rural and urban consumers of *Bt*-cowpea could be worth billions.

Surveys indicate that the average Nigerian consumer buying cowpea mostly for resale does not have a preference for any of the types of cowpea and would derive the same level of satisfaction from *Bt*- or conventional cowpea. The aggregate results across rural producers and consumers in

Table 4 Estimated gross benefit from *Bt*-cowpea in Niger

		Gross benefit from <i>Bt</i> -cowpea		
Rural consumers and producers	1 652 306 648 908	FCFA/year	3 055 752 790	US\$/year
Urban consumers	52 872 561 407	FCFA/year	97 781 775	US\$/year
Total benefit from <i>Bt</i> -cowpea—Niger	1 705 179 210 316	FCFA/year	3 153 534 565	US\$/year

Niger implies a willingness to pay a premium for *Bt*-cowpea, and this translates into a total benefit of \$US 3 billion with the adoption of *Bt*-cowpea (Table 4). Health reasons (which includes the *Bt*-cowpea is safer than conventional cowpea because it contains no insecticide) could explain the predicted behavior of the average urban consumer in Niger. The total gains for both producers and consumers with the introduction of GM cowpea in Niger would be US\$ 3 billions/year.

The estimated economic impact of *Bt*-cowpea in Nigeria—the largest cowpea-producing nation in the world, is presented in Table 5.

We conclude from the modeling that rural producers and consumers in Nigeria would experience a welfare gain of about \$US 5.1 billion once *Bt*-cowpea became available in Nigerian rural markets. Two reasons could explain why the average rural household in Nigeria might prefer *Bt*- to conventional cowpea:

1. *Bt*-cowpea is safer than conventional insecticide-sprayed cowpea in terms of consumption.
2. *Bt*-cowpea would increase the income of the rural farm household and therefore, increase its welfare.

The model predicts a gross welfare gain of about \$US 3.3 billion for all urban consumers in Nigeria once *Bt*-cowpea is made available in Nigerian urban markets. This assumption is based on the survey results that were conducted in Kano, Sokoto, and Maiduguri which showed that Maiduguri consumers tend to discount

Bt-cowpea, contrary to consumers in Kano and Sokoto who on average tend to prefer *Bt*- to conventional cowpea.

3.2.2 Efforts toward sustainable biotechnology opportunities in West Africa

In the United States and other countries where GM crops have been deployed, viable markets have developed and sustainable business models have emerged (James, 2006). These benefits have been especially evident for low-resource farmers in developing countries (Huesing and English, 2004). In many such environments, GM crops have proven profitable both for seed producers and farmers and have provided benefits to consumers such as reduced mycotoxin levels in foods (Hammond *et al.*, 2004). To raise awareness of needs and opportunities associated with GM crops in Africa, a workshop on “Appropriating Biotechnology for Investment Opportunities in Nigeria” was organized by IITA, the Nigerian Agricultural Biotechnology Project (NABP), the National Biotechnology Development Agency (NABDA), Ahmadu Bello University (ABU), and the Sokoto State Ministry of Agriculture and Natural Resources, and sponsored by USAID. The workshop laid the foundation for a sustainable biotechnology program in Nigeria by building institutional and scientific capacity to conduct research, implement priority regulatory guidelines and policies to create an environment for biotechnology development, and create awareness

Table 5 Estimated gross benefit from *Bt*-cowpea in Nigeria

		Gross benefits from <i>Bt</i> -cowpea		
Rural consumers and producers	658 038 817 706	NAIRA/year	5 131 907 332	US\$/year
Urban consumers	422 491 532 978	NAIRA/year	3 294 923 244	US\$/year
Total benefit from <i>Bt</i> -cowpea	1 080 530 350 684	NAIRA/year	8 426 830 576	US\$/year

of the benefits of biotechnology (C. Fatokun, personal communication 2006).

3.2.3 Adoption, perceptions, and profitability studies of conventional cowpea in West Africa

The introduction of *Bt*-cowpea into West Africa will necessarily occur in the context of a long-established process of cowpea improvement through traditional breeding (Eicher *et al.*, 2006). To assess what may await *Bt*-cowpea, a survey explored farmers' perceptions of cowpea pests in three different agroecological zones in Benin, particularly the legume pod borer, *M. vitrata* (Adetonah, 2005). Most of the farmers report that they start spraying to control insect pests 3 or 4 weeks after sowing. A little over half reported using synthetic insecticides recommended for cotton, while less than a quarter use synthetic insecticides recommended for cowpea. Others use botanical insecticides. A large majority of farmers were able to recognize *M. vitrata* larvae. Lower percentages of farmers were able to recognize adults or knew of the link between adults and larvae.

A study carried out in two agroecological zones in southern Benin demonstrated that the use of some chemical pesticides without adequate protection would expose farmers to headaches and respiratory, skin, eyes, and stomach ailments. Misuse of pesticides is a widespread problem in the developing world, including Africa, and farmers need more information and awareness about the health hazards linked to pesticide misuse as well as alternative pest control techniques like botanicals (IITA/Purdue University, 2005). This highlights the need for alternative technologies for the control of cowpea insect pests.

A third producer study indicated that the profitability of cowpea cropping systems depends mainly on the varieties used (local or improved), the cropping and management practices (use of chemicals including fertilizers and pesticides), and the access to input and output markets (Aïtchédjé, 2001). The results showed that only cropping systems using improved cowpea technologies—mainly improved varieties—were profitable even under tight credit constraints compared to local technologies (local cultivars and current storage techniques). A profitable

cowpea technology is composed of an improved variety and a chemical insecticide. The added value (gross margins) on cowpea production systems is mainly due to higher yields from the improved varieties. The pesticide used for field treatment and the storage technologies used after harvest can make a significant difference (Aïtchédjé, 2001). Financial benefits are probably higher because environmental and health-related costs, including lost workdays, associated with pesticide use were not taken into consideration in this financial profitability analysis. The misuse of pesticides, in general, has been causing deaths every year in the cotton- and cowpea-producing areas of Africa. These factors should be used by farmers in assessing the benefits of using pesticides.

3.2.4 Requirements for cowpea export and quality assurance

An exploratory market study of cowpea products in Ghana using data from case studies shows that cowpea flour, the main value-added product, is typically sold in bulk or in unbranded small packages through retail and wholesale outlets and directly to consumers including individuals, institutions, and the catering industry. Cowpea flour is less prone to insect pest attack than are whole cowpeas and consequently is a major source of food during the dry season and the period between harvests. However, the growth in the dietary share of cowpeas has been constrained by long preparation time and labor requirements, undesirable product characteristics including beanie flavor, low digestibility, and abdominal distress as well as postharvest grain losses to insect pests. There are several cowpea foods based upon cowpea flour and these provide a varied nutritious diet and have added desirable attributes, which include availability, easy cooking, and good taste. Although a high proportion of food processors are aware of new cowpea utilization technologies that are being developed, only a low percentage can expand their businesses to accommodate these new technologies. The full impact of new utilization technologies will be realized over several years and only following substantial private capital investment in processing, marketing, and strategic promotional activities. The market study in Ghana also established consumer preference for selected

product attributes measured in terms of responses to “agree/disagree” to declarative statements about selected product attributes including cooking quality, availability, taste, keeping quality, and comparison with soy flour (Nyankori, 2002). In many areas of Africa fresh cowpea leaves are regularly harvested and consumed often as a part of the typical “sauce” (Bean/Cowpea CRSP West Africa Mission).

3.2.5 Women and cowpea in Africa

In Africa, cowpea is a major source of cash income for both rural and urban women who are involved in cowpea-based food sales. (Okike, 2000). In Cameroon and Senegal, for example, most of the cowpea green pod marketing is handled by women. In other African countries, women harvest and sell cowpea to retailers or consumers at markets or on roadsides. In northern Nigeria, women are involved in cowpea production, cooking, and small ruminant feeding with cowpea hay (CGIAR, 2000). Women use CRSP storage technologies, particularly solar heaters, because they often do not have access to storage insecticides (Bean/Cowpea CRSP, 1997). A rapid appraisal survey of adoption of cowpea varieties and storage techniques carried out in 1996 in the northern Peanut Basin of Senegal indicated that both men and women use the improved varieties and the CRSP-developed metal drum technology for grain storage. Recent studies have revealed widespread adoption of another CRSP technology, bagging the grain in multiple plastic bags (M. Bokar, unpublished)

3.2.6 Remaining challenges

Numerous challenges to enhancing the cowpea value chain in sub-Saharan Africa remain. These include the participatory development and diffusion of improved cowpea varieties adapted to changing rainfall patterns, environmentally sound pest control, value addition, and market access. The Bean/Cowpea CRSP, IITA-PRONAF (Projet Niébé Pour l’Afrique), and national agricultural research and extension systems have contributed to these challenges through research and stakeholder capacity building. As has been demonstrated with

other crops, biotechnology as applied to cowpea has the potential to contribute to a significant increase in productivity and improvement in quality and competitiveness of cowpea-based products. Consumer preferences will be important in developing products with high potential to be adopted by farmers and other end users. Integrated pest management including resistance to pests like *Maruca*, which is not effectively controlled by conventional breeding or pesticide, will be a key for cowpea competitiveness for trade (lower pesticide) and lower health costs due to a significant decrease in toxic pesticide misuse.

Pea

Kevin E. McPhee

USDA-ARS, Pullman, WA, USA

1. INTRODUCTION

Pea (*Pisum sativum* L.) is an important crop worldwide and ranks second only to dry bean in worldwide production (FAO, 2006). It is consumed as a staple in many developing countries or fed to livestock for its nutritional value. In addition to its agronomic benefits and nutritional value, pea has served as the subject of numerous genetic studies and as a model for plant physiologists for more than one century. Pea has been chosen for these studies due to its wealth of genetic variation, short generation time, and ease of culture. These characteristics led to Mendel's choice of pea for his experiments and, though others worked with pea previously, Mendel is often credited as being the first to study the genetics of pea when he discovered the Laws of Segregation and Independent Assortment (Mendel, 1866).

Genetic study of pea continued during the 20th and 21st centuries and has traversed many landmark achievements. A myriad of simply inherited genes have been characterized and assembled into the seven linkage groups. Application of modern molecular DNA technologies toward genetic mapping in pea has produced a number of dense genetic maps and identification of specific markers linked to genes of agronomic importance that can be used for marker-assisted selection (MAS). Discovery of traits adversely affecting production and quality of pea has been shown to suffer from limited favorable genetic variation in germplasm. As a result, application of gene technology to introduce novel genes from

distant or unrelated species has been used to overcome these production constraints. A detailed description of this technology to pea improvement is the subject of this contribution.

1.1 History, Origin, and Distribution

Pea is a cool season annual legume crop that originated in the Near East and Mediterranean regions and has been grown since early Neolithic times (Zohary and Hopf, 1973). Evidence from carbonized remains indicates that pea has been cultivated with cereal crops, such as wheat and barley, since domestication. Limited historical evidence makes it difficult to determine the exact location of domestication; however, soon after domestication pea and other legumes spread to other parts of the world with the movement and activities of man. Currently, pea is produced on all continents except Antarctica. Pea was established in cool-temperate areas of Europe and the former Soviet Union as well as India and China. Introduction into North America occurred soon after discovery by Columbus (Hedrick, 1928).

1.2 Botanical Description

The genus *Pisum* is a member of the family Papilionaceae tribe Viciae and is composed of two species, *P. sativum* L. and *P. fulvum* Sibth. and Sm. The species *P. sativum* includes five subspecies, *P.s. ssp. sativum*, *P.s. ssp. elatius*, *P.s. ssp. humile*, *P.s.*

ssp. *Arvense*, and *P.s. ssp. hortense*. The literature indicates that ssp. *elatius* and ssp. *humile* are the progenitors of cultivated pea *P.s. ssp. sativum* (Zohary and Hopf, 1973). *P. sativum* ssp. *arvense* includes the field pea and the “Austrian” winter pea, both possessing colored flowers and variously pigmented seeds. *P. sativum* ssp. *abyssinicum* is a unique subspecies derived from Ethiopia and has been reported to have very narrow genetic base (Weeden *et al.*, 2004).

Genetic composition of pea is approximately 4800 Mbp (mega base pair) spread across $2n = 2x = 14$ chromosomes. The first karyotypes were presented as early as 1931 (Lewitsky, 1931, as cited by Blixt, 1958). The standard karyotype of pea is based on the type line, L110, following improvements over earlier procedures of Caroli and Blixt (1953) (Blixt, 1958; Hall *et al.*, 1997). Centromere location in chromosomes 1 and 2 is metacentric, while in the remaining five chromosomes it is submetacentric. Chromosomes 4 and 7 contain secondary constrictions and possess satellites. *Pisum fulvum* contains a third secondary constriction on chromosome 5 (Ben Ze’ev and Zohary, 1973). Chromosomes 2 and 5 have experienced a translocation event, referred to as the Hammarlund translocation (summarized by Kvostova, 1983). Numerous other chromosomal rearrangements have also been reported (Lamm and Miravalle, 1959; Kvostova, 1983; Folkesson, 1990a, 1990b).

1.3 Economic Importance

Dry pea production worldwide has averaged 11 million metric tons on slightly greater than 6 million hectares during the past decade (FAO, 2006). Fresh pea production is largely controlled by private industry and it is difficult to estimate the production and area due to proprietary issues and lack of reporting in other countries. Pea plays an important role in crop rotation in cereal-based cropping systems by providing an opportunity to break cereal disease cycles, control grassy weeds, and improve soil tilth and fertility through association with the soil bacterium, *Rhizobium leguminosarum*, which fixes atmospheric nitrogen into ammonia for use by the plant. Residual fixed nitrogen is available to subsequent crops

reducing the need to apply supplemental sources of inorganic nitrogen.

Rich genetic variation in pea has led to the development of many market classes including yellow or green cotyledon dry pea, wrinkle-seeded fresh peas for canning or freezing, edible-podded peas, and most recently the snap pea. All market classes harvested as fresh product are used for human consumption while the dried pea crop is used predominantly as an animal feed, but is also a component of soups for human consumption. In addition, the harvested dry pea can be processed industrially for starch or protein preparations. A more specialized type of green pea, the marrowfat pea, is also produced and has extremely large and irregularly shaped seeds. The marrowfat pea is used in snack food preparations in the Far East and in a thick soup preparation in the United Kingdom referred to as “mushy peas.”

Legumes in general are nutritionally rich. Pea contains 18–33% protein, 4–7% fiber, and 37–49% starch and is an excellent source of carbohydrate, minerals, and vitamins. Though dry peas are nutritionally rich, they contain antinutritional factors, which detract from their value for some uses. For example, trypsin inhibitors reduce the feed value when fed to livestock and presence of raffinose family oligosaccharides may cause intestinal and social discomfort when dry pea is consumed for food. Presence of phytic acid limits the availability of mineral elements and other dietary components including starch and some protein.

The most widely produced pea in the world is the yellow cotyledon dry edible pea, although the green cotyledon dry pea is quite popular in some regions. Green dry peas are typically split and used almost exclusively for human consumption while yellow peas are primarily used as a supplement in animal rations. A portion of yellow peas are used for human food, but due to limited reporting from many developing countries it is difficult to estimate an exact quantity. The Austrian winter type pea with colored flowers and pigmented seed is another form of dry pea which when harvested at maturity is commonly used as an ingredient in bird feed. Due to its excessive biomass production, the Austrian winter pea is commonly used as a green manure crop to improve soil tilth and fertility. A rather minor dry pea type produced for the snack industry in the Orient is the marrowfat pea. It is also harvested dry and is characterized by

extremely large and irregularly shaped seed with a dimpled surface.

1.4 Traditional Breeding

Traditional breeding approaches to genetic improvement of pea have been remarkably successful. Pea breeding has taken advantage of the rich genetic variation available in the germplasm. Breeders have achieved modest increases in yield and have altered plant morphology significantly over the past three decades. Early varieties were characterized by a long vine, normal leaflet morphology, and ranging growth habit. The canopy collapsed at maturity as the plants lodged making it difficult to harvest and creating an environment favorable for disease development. Discovery of the single gene mutation, *af*, for tendrilled leaf morphology led to development of modern semi-leafless cultivars with improved standing ability. The semi-leafless morphology

(*afafStSttltl*) combined with the recessive *le* allele for shortened vine length resulted in a plant type that was sturdy and remained upright throughout the growing season. Improved stem strength properties and the ability of tendrils from neighboring plants to intertwine and provide mutual support resulted in the erect canopy. The upright canopy allows greater air flow reducing disease incidence and improves harvest ease.

The pea crop is challenged with both biotic and abiotic stresses. Biotic stress agents include insect pests and fungal, viral, and bacterial pathogens (Table 1). Genetic resistance is present in available germplasm for many of the pathogens; however, little genetic resistance to insect pests is currently available. Plant breeders have introduced resistance to many pathogens, especially those controlled by single genes, but many of the more quantitatively inherited resistances have been more difficult and remain a focus for future improvement. The most devastating pathogen worldwide is *Aphanomyces euteiches* (Drechs.) and

Table 1 Biotic stress agents constraining US dry pea production

Biotic stress	Causal organism	Resistance mechanism
Disease		
Fusarium root rot	<i>Fusarium solani</i>	Polygenic

genetic resistance is controlled by several loci and is inherited in a quantitative manner (Pilet-Nayel *et al.*, 2002). Genetic resistance has recently been identified and is currently being introduced into new cultivars in several breeding programs. Powdery mildew, caused by *Erysiphe pisi* DC. is important in all pea production regions and is controlled by a single recessive gene, *er*; however, it has been hypothesized that a second gene may also be involved in resistance (Tiwari *et al.*, 1997). The *er* gene is durable and has effectively conferred resistance since its initial description (Harland, 1948). Genetic resistance to the important viruses is simply inherited and controlled by single genes; *En* for pea enation mosaic virus, *lr* for bean leaf roll virus and *sbm-1* for pea seed borne mosaic virus, and have been incorporated into many modern cultivars.

Seed quality traits are less well characterized genetically, but breeders have been able to select improved types through visual selection. Dry pea is sold into two primary markets for food or feed and each requires different quality attributes. The food market is driven primarily by visual appearance of the seed's size, shape, and color. However, splitting ability and integrity of whole seed during rehydration and canning are also important quality criteria for the food market. Splitting ability comprises traits including, dehulling efficiency and resistance to cracking and breakage. Retention of bright cotyledon color is a primary quality criterion for all peas, both yellow and green cotyledon types, in food markets. Quality of fresh market peas for freezing and canning is based on bright, attractive color, flavor, seed size, and skin toughness as it impacts seed integrity through processing. Resistance to bleach or "blonding" is important for all green pea markets, dry or fresh market types. Green cotyledon pea seed harvested dry can bleach in the presence of high humidity or rain and intense sunlight. Bleached seed in a harvested sample cannot exceed 1.5%, 3.0%, or 5.0% to be graded no. 1, 2, or 3, respectively. Excessive bleach reduces the quality and value of the crop to the grower.

Quality criteria for the feed markets focus on the internal seed composition rather than appearance. Energy value derived from the starch component, protein content, amino acid profile, and presence of antinutritional factors, such as phytic acid and trypsin inhibitors, which reduce palatability and

digestibility of the pea seed are also important. Significant genetic variation for protein content is available in germplasm, but only modest effort has been made to increase seed protein content.

Modern breeding programs either use bulk population, pedigree selection, or a combination of these procedures to identify superior breeding lines (Muehlbauer *et al.*, 1988). The bulk population method has the advantage of easy population maintenance while allowing natural selection to occur prior to selection of superior nearly homozygous types in the F₄ or F₅. A disadvantage of the bulk procedure is that certain genotypes may be lost reducing the range of variation present for selection. The pedigree method maintains a wider range of genetic variation initially present and allows specific undesirable genotypes to be removed from the population. The pedigree method is time consuming, labor intensive, and requires that individual plants be space planted for data collection. Wide plant spacing has the disadvantage that data collected may not be representative of growth in a solid stand.

Population improvement in pea has been accomplished using biparental mating or backcrossing followed by selection and has been successful in transferring disease resistance from landraces and wild germplasm into adapted legume germplasm. Three-way and double crosses are also used to combine useful traits among diverse germplasm. Male sterility is present in *Pisum* germplasm; however, due to limitations associated with cross-pollination in the male sterile parent, development of hybrid cultivars has not been successful. Recurrent selection, though time consuming and laborious in self-pollinated crops, has been used to pyramid favorable alleles for disease resistance (Lewis and Gritton, 1992). Specific crossing designs, such as the diallel and top cross, are commonly used to combine various traits and to determine combining ability among parental types (Griffing, 1956).

Mutation breeding has been used worldwide for improvement of grain legumes through increased genetic variation and creation of novel alleles. Pea cultivars resulting from mutagenesis have been released with improvements including increased yield, lodging resistance (afila leaf trait), larger seed, increased protein concentration, and modified maturity (Micke, 1988a). Mutation breeding of pea has been centered in many European

countries including Sweden, the Netherlands, Germany, Italy as well as several eastern European countries and Russia (Micke, 1988b).

Conventional breeding methods have been successful in improving pea germplasm toward development of superior cultivars. However, genetic studies have shown that improvement of several important agronomic characters in pea is difficult and would benefit from MAS. Detailed genetic maps have been generated for pea placing many genes of interest on individual linkage groups and associating them with DNA markers derived from several methods (Weeden *et al.*, 1998; see McPhee, 2006 for a review). The diversity of procedures employed to develop the markers currently available limits the application of MAS in breeding programs. Optimum application of MAS requires that markers be (1) tightly linked to the trait of interest, (2) based on one or few technologies, and (3) co-dominant to allow selection in early generations. Loridon *et al.* (2005) reported a consensus map of pea that comprises randomly amplified polymorphic DNA (RAPD) and co-dominant microsatellite markers that will not only serve as a reference map for the research community, but also offers a framework to which additional co-dominant markers can be placed near important disease resistance or other genes of agronomic importance.

Major accomplishments for plant breeding in pea include improved agronomic performance through an erect plant type with an upright canopy, multiple disease resistance, and improved crop quality for current markets. Improved disease resistance is primarily for those traits where single genes are responsible for resistance and additional effort is needed for those traits controlled in a quantitative manner. Though significant improvements have been made through conventional breeding, lack of favorable genetic variation or inability to identify superior selections provides opportunities for genetic modification using genes introduced from beyond natural hybridization barriers.

1.5 Limitations of Conventional Breeding and Rationale for Transgenic Breeding

Traditional plant breeding efforts in pea has made significant advancements; however, many impor-

tant traits suffer from limited genetic variation and knowledge of genetic control mechanisms. Specific avenues for improvement include increased content of sulfur-containing amino acids and reduced level of antinutritional compounds, such as phytic acid, galactose sugars RFOs (raffinose family oligosaccharides), and trypsin inhibitors. Though genetic resistance is present in available germplasm, application of broad-spectrum virus resistance may be possible based on common genetic mechanisms among viruses that affect peas. Pea has a significant advantage to other legumes and crops in general due to its broad use as foodstuff in developing countries and its reputation as a healthy food. Gene modification to improve nutritional value through increased mineral or micronutrient content would be an effective means by which to address malnutrition in many undernourished populations. Starch modification in pea seed could be an effective way to convert pea to a functional food and thereby add value as a health food.

2. DEVELOPMENT OF TRANSGENIC PEAS

The primary objective of genetic transformation in pea, with few exceptions, has been to prove the potential for transformation and establish a functional system for genetic transformation (Table 2). A few genes of agronomic importance have been incorporated into pea with functional outcomes and, unfortunately, those which have been proposed for deregulation have been unable to overcome the regulatory hurdles.

2.1 Donor Genes

2.1.1 Bruchid resistance

Schroeder *et al.* (1995) transformed pea cv. Greenfeast with the α -amylase inhibitor (αai) gene from common bean (*Phaseolus vulgaris* L.) to induce resistance to *Bruchus pisorum*, an important seed pest. The coding region was engineered to include the coding region of αai flanked by the 5' and 3' regions of the PHA gene, *dlec2*, from bean. The selectable marker gene *bar*, flanked by the 35S promoter and ocs 3' terminator region were included in the transfer DNA (T-DNA). Explants were transformed according to procedures described in Schroeder *et al.* (1993).

2.1.2 Alfalfa mosaic virus (AMV)

Grant *et al.* (1998b) transformed six cultivars or breeding lines of pea, 94-A26, 'Bolero', 'Hadlee', 'Crown', 8554, and 89T46.UK. These lines represent the fresh processing, maple, and dry pea market classes. Two binary vectors were designed to transfer the AMV coat protein into pea. Both vectors included the *nos-nptII* gene for resistance to kanamycin as the selectable marker and AMV-cp coding sequence downstream of the 35S promoter. In addition to the 35S promoter, the second plasmid contained the tobacco mosaic virus (TMV) enhancer region immediately upstream of the AMV-cp coding sequence. Cotyledonary explants from field grown seed were used as explants and transformation was accomplished using *Agrobacterium tumefaciens* strain AGL1.

Timmerman-Vaughn *et al.* (2001) also transformed pea cv. Crown and two breeding lines, 94-A26 and 89T46.UK13, representing three different market classes; maple pea, fresh processing pea, and field pea, respectively. These lines were transformed with the AMV strain NZ1 coat protein coding sequence acquired by polymerase chain reaction (PCR) amplification from plasmid DNA. Two binary plasmids were used to transfer T-DNA to the plant. The first contained the AMV-cp downstream of the 35S promoter and the second contained the TMV Ω' enhancer in addition to the

35S promoter. Selection was accomplished using a *nos-nptII-nos* gene for kanamycin resistance. Immature cotyledons were used as explants (Grant *et al.*, 1995) and transformed with *A. tumefaciens*.

2.1.3 Pea enation mosaic virus (PEMV)

Chowrira *et al.* (1998) transformed pea cv. Sparkle with the PEMV coat protein coding sequence from an existing clone, pPCP4-5, flanked by the 35S promoter and a 3' *rcbs* terminator sequence. *In planta* transformation of axillary meristems was accomplished via microinjection and electroporation of decapitated plants. Selection was not conducted on the plants and R₁ progeny derived from seed harvested from shoots that developed from electroporated buds were tested for the presence of the PEMV-cp by PCR and southern hybridization.

2.1.4 Pea seed-borne mosaic virus (PSbMV)

Grant and Cooper (2003) report unpublished results of transforming 10 pea genotypes with three different constructs containing the PSbMV coat protein—two in the sense orientation and one with a nontranslatable sequence. Though independent transformed plants were obtained, none of the

primary transformants were resistant to PSbMV infection and the gene(s) were not inherited based on progeny analyses.

Jones *et al.* (1998) used four different constructs to transform the replicase gene, *Nib*, from PSbMV strain DPD1 (pathotype 1) into pea cultivar Puget to induce resistance to PSbMV. Transformation was accomplished using the procedure of Bean *et al.* (1997). Three constructs contained two tandem 35S promoters followed by the *Nib* coding sequence and the cauliflower mosaic virus (CaMV) PolyA terminator sequence. Construct #2 included a tandem repeat of the *Nib* coding sequence and Construct #3 included an inverted repeat of the *Nib* coding sequence. The fourth construct contained a *nos* promoter and *ocs3'* terminator surrounding the *Nib* coding sequence. Thirty-five independent transformants were generated with

one to three copies of the transgene and transformants with each of the constructs were recovered.

2.2 Methods Employed

Pea has been genetically transformed using two methods, *A. tumefaciens*-mediated and direct delivery through microinjection coupled with electroporation. Direct delivery using the gene gun technology has been attempted but only transient gene expression was reported (Warkentin *et al.*, 1992). The preferred method of genetic transformation in pea is through the use of *A. tumefaciens* (Figure 1). Although, microinjection and electroporation have been reported (Chowrira *et al.*, 1998), this methodology has not been adopted in the scientific community.

Figure 1 Stages of pea transformation via *Agrobacterium tumefaciens*. (a) Thin slices of immature embryonic axis, (b) explants on selection media, (c) putative transformed shoots on selection media, (d) transformed shoot being grafted to root stock

Early efforts in transformation of pea focused on identification of appropriate explant tissue and tissue culture procedures. Due to difficulties associated with regeneration through organogenesis and embryogenesis from callus generally in legumes intact meristematic tissue has been used as explant for genetic transformation, and *A. tumefaciens* is the selected vehicle for gene transfer. Efficiency of genetic transformation in pea ranges from <1% to 5%.

2.3 Selection of Transformed Tissue

Selection of transformed pea has been accomplished with both antibiotic and herbicide resistance genes. Antibiotic selection has been accomplished using *nptII* for kanamycin resistance and *hptII* for hygromycin resistance. Selection using herbicide resistance genes has been accomplished using *ahas3r* for resistance to chlorsulfuron and *bar* for resistance to Basta. Though kanamycin has been considered inadequate for selection, it has been used successfully at concentrations of 50 mg l⁻¹ (De Kathen and Jacobsen, 1990; Lulsdorf *et al.*, 1991; Polowick *et al.*, 2000), 75 mg l⁻¹ (Grant *et al.*, 1998a), and 100 mg l⁻¹ (Davies *et al.*, 1993; Svabova *et al.*, 2005). Hygromycin has been used at concentrations of 5–10 mg l⁻¹ (De Kathen and Jacobsen, 1990; Grant *et al.*, 1995; Bean *et al.*, 1997; Jones *et al.*, 1998), 15 mg l⁻¹ (Puonti-Kaerlas *et al.*, 1992), and 25 mg l⁻¹ (Lulsdorf *et al.*, 1991). Herbicide resistance to Basta conferred by the *bar* gene has been successfully used at concentrations of 10 mg l⁻¹ (Polowick *et al.*, 2000) and 15 mg l⁻¹ PPT (Schroeder *et al.*, 1993) (Figure 1c). The only report using the *ahas3r* gene for resistance to chlorsulfuron used a concentration of 10 mg l⁻¹ (Polowick *et al.*, 2000).

2.4 Regeneration of Whole Plant

Regeneration of whole plants occurs in two stages using current methodology. Shoots are generated from existing meristems in the explants and successively subcultured during selection. Once shoots are considered transformed they are either induced to root on a high auxin medium or grafted directly onto existing rootstocks in the greenhouse or growth chamber (Figure 1d). Induction of roots is rather time consuming and can take as long as

4–6 weeks, whereas grafting can be accomplished immediately. Both systems will incur some loss, but grafting can shorten the time required to produce T₁ seed by several weeks.

2.5 Testing

Identification of successful transformants among plants surviving selection in tissue culture has been accomplished using a variety of methods. Evaluation in the early attempts at transformation made use of the florescent nature of the β -glucuronidase (*GUS*) gene, *uidA*, and was tested in callus or cell extract (De Kathen and Jacobsen, 1990; Lulsdorf *et al.*, 1991). Phenotypic tests, such as fluorescence and herbicide paint assays, were used in later experiments where young plants were regenerated. As PCR became more routine, PCR-based methods were used to amplify a region of the inserted gene or the T-DNA to test the T₁ or primary transformant. Enzyme assays have been used as a means to test functionality and expression level of the gene. Final proof of transformation involves DNA or RNA blotting using probes derived from the T-DNA. Positive results from southern or northern blot tests in later generations showed both that the gene was heritable and that it was stably incorporated in genomic DNA.

Puonti-Kaerlas *et al.* (1992) were the first to report the inheritance of an inserted gene (*hpt*) in regenerated plants and progeny. They performed a comprehensive evaluation using phenotypic reactions, nucleic acid tests, chromosome analyses, and morphological inspections. R₁ seeds harvested from the primary regenerants were tested for resistance to hygromycin by placing a drop of hygromycin on the third leaf and recording the presence of local lesions. In addition, leaf explants were placed on media containing hygromycin and production of callus was recorded. R₁ plants were allowed to self, and R₂ seeds collected and tested for presence of the transferred DNA by southern blotting. Gene expression was tested based on northern blots using an *hpt* probe. Southern analysis showed that all hygromycin resistant R₁ and R₂ plants possessed *hpt* and those that were sensitive lacked the gene. They analyzed 12 R₁ or R₂ plants derived from two clones and all were shown to be tetraploid. They concluded

that the chromosome doubling occurred during tissue culture since analysis of the parents showed that they were diploid. Detailed morphological analysis of the transformants showed that for some traits the transgenic plants were significantly different than the control genotype, but that overall the deviations were slight. Various leaf measurements showed the greatest difference between the control and transgenic offspring. Variation among offspring clones derived from the same callus ranged significantly from values statistically different from the parents to those that did not differ significantly from the control.

Davies *et al.* (1993) tested for stable integration and expression of the transferred DNA using southern blots and PCR amplification of a portion of the *GUS* gene. They reported the selection and regeneration of 28 T₀ plants, which were derived from four independent transformation events. PCR evaluation indicated that all plants tested contained the transferred gene while the control did not produce a product. *GUS* positive plants were tested multiple times and were shown to confirm the reaction. Though a positive *GUS* reaction was observed in all instances, activity in one of the plants was significantly lower by as much as 50-fold. Pollen fertility among these lines was greater than 90% in three of the four clones, but was 29% in the fourth and seed set was only 17.1 seed per plant while the other three lines produced from 32 to 71.8 seed per plant. Southern blot analysis was performed with two probes, an internal probe and one that spanned the *GUS*/RB junction and showed the presence of multiple *GUS* genes in all four lines. The numbers of *GUS* genes, based on the internal probe, contained in three of the lines were 1, 5, and 20, respectively. A band was not detected for the fourth line using the internal probe, therefore, the positive result was due to the RB/T-DNA junction. Combined analysis of the digests and southern blots indicate that the four lines contained, 1, 3, or 5 independent loci. Those lines with more gene copies than independent loci contained tandem arrays of insertions.

Schroeder *et al.* (1993) used the *bar* gene for resistance to the herbicide, Basta, and tested for phosphinothricin acetyl transferase (PAT) enzyme activity among putative transformants. They performed northern blot analyses with a probe encompassing the entire *nptII* coding region. In addition to enzyme assays and northern blots

they tested the plants phenotypically using a leaf paint assay where individual leaflets were wetted with a solution of the Basta herbicide and localized reactions were recorded. PAT activity varied 20-fold among the lines tested and could be detected in progeny plants of the R₁ generation. They reported that the *bar* and *nptII* genes were transferred to the next generation following a 3:1 Mendelian ratio for presence/absence.

Grant *et al.* (1995) used the *bar* gene and *nptII* to identify transformants. Verification of gene insertion and expression were performed using enzyme and leaf paint assays similar to Schroeder *et al.* (1993). Transformation was confirmed by southern blot analysis using the *bar* and *nptII* genes as probes. Two primary transformants were evaluated cytologically and were shown to have the expected diploid chromosome complement of $2n = 14$. T₁ progeny from transformants for three of the lines showed expected Mendelian segregation ratios, while all plants from the fourth line were positive. It is possible that the 100% positive result was due to this line containing three copies of *bar*; however, few individual plants were available for testing. Regenerated plants were tested for the possibility that they were chimeric. This possibility was dismissed since only one pod (with two seeds) that was negative for the *bar* gene and the two seeds in that pod could have been negative by chance.

Bean *et al.* (1997) used the *bar* gene to identify transformants during culture and transformants were phenotypically verified using the herbicide paint assay and a PAT enzyme assay. Insertion into genomic DNA into primary transformants was accomplished by southern blotting with a 550-bp fragment of the *bar* gene from the plasmid, pJIT84. Segregation in the T₁ indicated that two of eight events segregated according to the expected 3:1 ratio while the remaining lines were chimeric with differing segregation ratios.

Jones *et al.* (1998) used the same procedure as Bean *et al.* (1997) and used leaf paint assays with PCR-based tests to confirm the primary transformants. DNA and RNA blots were also used to verify incorporation into genomic DNA and expression of the *Nib* gene. Progeny lines were tested through the F₃ (equivalent to T₃) and the gene was shown to be stably inherited and expressed. The plants that were tested and shown to be transgenic were shown to achieve equivalent plant height to the nontransgenic control.

Chowrira *et al.* (1998) did not use selection during generation of primary transformants (R_1). PCR analysis of 23 R_1 plants identified three with the expected band. These three plants were then tested by southern hybridization to confirm the PCR results. Plants testing positive by southern blotting were tested for protein level by western blotting. Progeny in the R_4 showed resistance to PEMV indicative that the coat protein gene was heritable and maintained function.

Evaluation of transgenic pea developed by Commonwealth Scientific and Industrial Research Organization (CSIRO) Plant Industry in Australia containing the α -amylase inhibitor gene, (αAI) for bruchid resistance is the most complete and comprehensive evaluation of transgenic pea with regard to expression, inheritance and of human and environmental impact. Schroeder *et al.* (1993) reported the stable integration of the amylase inhibitor gene from *P. vulgaris* in pea cv. Greenfeast and cv. Rondo. Verification of transformation included enzyme assays for PAT and nptII activity and Northern analysis for bar expression. Inheritance of the *bar* and *nptII* was tested in the R_1 and fitted the expected 3:1 (presence: absence) ratio. Inspection for morphological aberrations indicated that the R_0 and R_1 plants did not have adverse effects from insertion of the T-DNA.

Schroeder *et al.* (1995) grew five of 18 transformed plants to the T_1 and used a nondestructive test for presence of the α -ai protein in the cotyledon. Individual seeds expressing the protein were sown to produce T_2 seed for bioassays with *B. pisorum*. Six plants from one of the lines (F10) selected for high expression levels of α -AI grown to the T_4 along with six control plants were used in a second bioassay experiment. Six to eight weevil eggs were placed on the pods of the test plants such that the larvae could hatch and infest the seed. Emergence of adult weevil was monitored regularly for 140 days and emergence of adults was recorded. Southern, northern, and western analyses were conducted to quantify gene expression in transgenic seeds. Homozygous T_4 plants were indistinguishable from nontransgenic control plants and seed yield was equal.

A subsequent study by Morton *et al.* (2000) investigated the effectiveness of a variant of the α -AI gene, $\alpha AI-2$, on pea weevil development and the potential impact on strategies for crop protection in the field. The $\alpha AI-2$ gene is less

effective than $\alpha AI-1$ and serves to delay emergence of the adults by as much as 3–40 days, but does not kill the larvae. Deployment of the $\alpha ai-1$ gene would provide severe selection pressure on the bruchid risking development of a resistant population. Morton *et al.* (2000) suggest that even though $\alpha AI-2$ does not provide complete resistance, combining it with $\alpha AI-1$ would not effectively reduce the selection pressure since it functions in a similar manner. Feeding trials using peas expressing $\alpha AI-1$ indicated no adverse effects on rats (Pusztai *et al.*, 1999) and field trials conducted in three diverse locations and over several years demonstrated that agronomic performance of the transgenic plants was equal to the nontransgenic controls and that the resistance to the seed weevil was effective.

The most recent evaluation of peas expressing the $\alpha AI-1$ gene involved feeding trials with broiler chickens (Li *et al.*, 2006). This study indicated that the transgenic peas did not adversely impact health or protein utilization of the chickens; however, starch digestion was reduced indicating a limitation to the use of transgenic peas expressing $\alpha AI-1$ in diets of monogastric mammals. A similar result of normal protein digestion and reduced starch utilization was reported in a feeding trial with pigs using the same transgenic seed line (Collins *et al.*, 2006).

In summary, transgenic peas expressing the $\alpha AI-1$ gene were created using the *A. tumefaciens*-mediated protocol and were tested extensively for gene expression, inheritance of the introduced gene through at least five generations, evaluated in field trials for efficacy of the $\alpha AI-1$ protein against seed weevil, and evaluated in feeding trials to determine the ultimate utility and impact of transgenic pea on the environment and in feed rations. Evaluation of pea seed expressing the $\alpha AI-1$ gene is the most extensive and complete example of its kind in the literature.

2.6 Regulatory Measures

Advent of the worldwide web has opened doors to easy access of information on a wide variety of topics. The regulatory policies in place within the United States and internationally to monitor and regulate genetically modified crops are no exception. The three primary regulatory agencies in the United States are APHIS (Animal and Plant

Health Inspection Service), EPA (Environmental Protection Agency), and FDA (Food and Drug Administration). Each of these agencies has websites containing a wealth of information on the regulatory processes they use to ensure that no adverse effects on the environment or human health will occur as a result of the release and production of a new, genetically modified organism.

The three US agencies act in a coordinated way to ensure that human health and safety of the environment is maintained. APHIS is charged with regulation of plant pests and plants. EPA is charged with regulation of microbial/plant pesticides and new uses of existing pesticides and the FDA is charged with regulation of food, feed, and food additives. A document entitled, Coordinated Framework for Regulation of Biotechnology, published in the Federal Register issue 51 Fed. Reg. 23,302, 23,302 (1986) prescribes how products of US biotechnology will be reviewed and what federal agencies will review them. In general, separate but coordinated oversight is carried out by the United States Department of Agriculture (USDA), EPA, and FDA, depending upon the gene and host crop and their respective roles are to ensure that the new genetically modified crop is safe to grow (APHIS), safe to the environment (EPA), and safe to eat (FDA). Plant incorporated pesticides (PIP) include the gene and the enzyme produced as the result of expression of that gene and are regulated by EPA. FDA policy regards the PIP as a food additive and as a result has authority to regulate the new crop.

Criteria that must be met prior to deregulation include documentation that no risk to human health, nontarget organisms, and the environment exists. In addition, the potential for gene flow must be negligible and a management plan that minimizes development of pest resistance must be developed. EPA assesses potential effects associated with a plant-incorporated protectant, including toxicity, allergenicity, and skin and eye irritation, as well as long-term effects including cancer, birth defects, and reproductive and neurological system disorders. These potential effects are also assessed in relation to the public's potential exposures to these pesticides and take into account all potential combined sources of the exposure (food, drinking water, etc.) to determine the likelihood that a person would be exposed at levels that would pose a health risk.

It is critical that these factors that are used to evaluate a novel genetically modified crop be taken into consideration at the outset of a given research project. As genetic transformation can be a long and expensive process, especially for legumes, it is in the best interest of the research project to design experiments that minimize adverse effects and remove potential road blocks to deregulation. In addition to the health and environmental concerns listed above, proprietary issues for all processes and components must be reconciled prior to complete implementation and deregulation.

3. FUTURE ROAD MAP

3.1 Expected Products

Dry pea production is challenged with a number of biotic and abiotic stresses. As new information is generated regarding resistance mechanisms and novel traits are discovered to introduce resistance, it is expected that new genetically altered pea varieties addressing plant stress could be developed. Drought is a major limiting factor for production in many regions worldwide. In addition, salinity and/or mineral toxicity are production constraints that may be addressed through novel gene introduction.

Seed quality issues such as seed size, digestibility, and appearance are important for marketability and consumer acceptance. Altered expression of invertase has been studied in chickpea and could be applied to pea to increase seed size for niche market classes. Starch modification toward altered digestibility and functional starch is a novel concept that has significant dietary application. Increased protein content and improved amino acid composition through increased content of S-containing amino acids, cysteine, and methionine, would benefit both food and feed uses.

Broad-based virus resistance and resistance to fungal pathogens through incorporation of anti-fungal genes offer opportunities to significantly improve crop production and possibly return pea production to areas where disease pressure has made production impossible.

Functional genomics and gene discovery in pea will continue to expand and be a focus of research. Virus-induced gene silencing (Constantin *et al.*, 2004) and RNAi (RNA interference) applications

hold great promise in all crop species, but transformation efficiency will need to be improved before this technology can be fully implemented. Knockout mutants resulting in the reduction or elimination of antinutritional factors such as trypsin and chymotrypsin inhibitors, raffinose oligosaccharides, and phytic acid would improve digestibility and consumer appeal.

3.2 Addressing Risks and Concerns

Risks and concerns related to development of transgenic pea varieties to human health and the environment depend largely on the introduced gene. Careful selection of the gene and thorough evaluation of the new plant will significantly reduce the chance of adverse effects when the new variety is produced. Traditional cropping systems and production practices may change with the possibility that herbicide resistance is introduced into pea. Impacts of this technology have been debated and are well documented.

Pea is a self-pollinating crop with <1% outcrossing that reduces the risk of gene transfer via pollen. Escape of a transgenic crop into roadsides or neighboring fields is of concern with regard to creation of a weed problem that cannot be controlled. Escape of pea from cultivated areas has not been observed in North America and combined with the low levels of outcrossing make pea a relatively low risk crop to the environment and for deployment of transgenic varieties.

A primary concern over transgenic crops is that unintended effects on plant phenotype and seed content may occur as a result of introducing a foreign gene. Charlton *et al.* (2004) reported a novel application of proton nuclear magnetic resonance (NMR) to quantify metabolite differences in leaf extracts and using that information to test the hypothesis that introduction of a gene results in marked differences in a transgenic plant. Comparison of transgenic lines, null transformants (plants lacking the gene yet passing through the tissue culture process), and wild-type plants showed that significant differences could be detected between the three plant types, but that these differences could not be attributed solely to introduction of the gene. Due to the wide variation present among wild-type samples and reduced significance of differences

between the wild type and later generations of transgenic lines they concluded that differences detected by NMR were likely due to passage through tissue culture and progressive loss of epigenetic effects. They also suggest that NMR may be a viable means by which to show that transgenic pea lines lie within the normal range of variation seen in wild-type plants.

3.3 Expected Technologies

Transformation efficiency in the legumes is very low. Variability in efficiency is contributed by genotype, binary plasmid, introduced gene, and variability among personnel. Transformation efficiency in pea ranges from <1% to as high as 5% and methods to improve efficiency are needed to expand application of the technology.

Selectable marker genes that are currently available are adequate and are quite effective. It will be important in future applications of transformation technology that twin binary plasmids are used such that the marker gene and the gene of interest are inserted on independent T-DNA. The independent T-DNA has a likelihood of being incorporated at different positions in genomic DNA. Genetic segregation of these genes in progeny allow for selection against the selectable marker removing concerns over these genes in the transgenic variety.

3.4 Public Perceptions and Political and Economic Consequences

Worldwide importance of pea as food crop offers an opportunity for pea to serve as a vehicle to deliver important added dietary components to malnourished populations. Public acceptance of genetically altered crops for food use will provide resistance to adoption, but if these issues can be overcome this technology could serve as an invaluable tool for human health.

1. INTRODUCTION

1.1 History, Origin, and Distribution

Vicia faba (faba bean) was not among the very first domesticated crops. It was probably introduced into agriculture only in the late Neolithic period (Körber-Grohne, 1987). Cubero (1974) concluded that the center of origin was in the Near East, Iraq, and Iran, and secondary centers evolved later on in Afghanistan and Ethiopia. Before 1000 BC, the culture of faba beans was already very established in Europe, including Britain. Large-seeded types are of recent origin and they were probably developed only 1000–1200 years ago in East Iraq, and from there spread to Asia, across North Africa to Europe, and eventually to America. In China, the crop seems to have arrived only after 1200 AD. The faba bean reached Mexico and South America by the Spaniards. From then on, it experienced there an independent evolution (Körber-Grohne, 1987; Bond, 1995). Several gene bank accessions with promising agronomic features originated from Ecuador. These are mostly large-seeded types. The more recent history has to mention the comprehensive reports of Muratova (1931), Sirks (1931) and Hanelt *et al.* (1972) on genetics, systematics, taxonomy, history, and geographical topics (Bond, 1995).

1.2 Botanical Description

The intraspecific diversity is mainly described by use of seed size. Persoon (1807) described the small-seeded group as *V. faba minor* (roundish seeds of up to 0.6 or 0.7 g weight per seed), the medium-large-seeded group as *V. faba equina* (single seed weight less than about 1 g) and *V. faba major* with its impressive, large, and flat seeds weighing more than 1 g per seed. The name “field beans” indicates to the small and medium sized types, whereas “broad beans” denotes *V. faba major*. Today, often “faba bean” is used to address the species in its total diversity. A wild ancestor of faba bean is not known, and the related vetch *Vicia narbonensis* is considered as the nearest relative to *V. faba* (Zohary and Hopf, 1973). Based on restriction fragment length polymorphism (RFLP) and polymerase chain reaction (PCR) data, more recently Van den Ven *et al.* (1993) placed *Vicia peregrina* and *Vicia michauxii* into the direct taxonomic neighborhood of *V. faba*. These related vetches have seven chromosomes. *V. faba* belongs with *Vicia villosa* and *Vicia sativa* to the genus *Vicia*. With *Lens culinaris* and *Pisum sativum*, it belongs to the tribe *Vicieae* and only at the family level of *Fabaceae* it is united with the *Phaseolus* bean, the soybean and with the lupines (Sitte *et al.*, 2002).

The faba bean crop is annual, sown either in autumn or in spring. It bears a strong, hollow, tetragonal erect stem, with zero or up to five (or even more) basal branches arising from basal leaf axis. There are only noneffective rudiments of tendrils at the leaf tip. Different from pea, stipules are very small, with a distinct black stipule spot on the stipule's down side. The bean has got a robust tap root with profusely branched secondary roots. Nevertheless, the rooting system is not as voluminous as that of cereals like oats or wheat. The roots bear the typical nodules formed by *Rhizobium leguminosarum*, as expected for it being a leguminous species. The first, juvenile leaves bear two leaflets. After four or more nodes the maximum number of leaflets (typically six) is reached. The first, lowermost inflorescence is located in the axis of a leaf with at least four leaflets, inserted on the stem as low as at the fourth node or several nodes later (higher). Two to more than eight flowers per inflorescence occur. The wild type flower color is white with a soupcon of pink traces and a very distinct, satin black spot on both wing petals (Figure 1). Brown, violet, red, and further grades of flower colors exist. Totally white flowers are a pleiotropic effect of an allele for zero tannin in the seed testa, accompanied by grayish testa color instead of buff testa and by absence of the wild type stipule spot. One to two pods with three or four seeds are to be expected per inflorescence; one plant may yield far more than 12 pods, distributed across more than six nodes. In germplasm used for human consumption, often very few, very large pods per plant are realized, with more than 20 cm pod length, more than six

Figure 1 *Vicia faba* flower with white flag petal and black spot on wing petal

Figure 2 Karyogram of *Vicia faba* [Reproduced from Fuchs *et al.* (1998). © Springer]

seeds per pod and more than 1 g weight per seed. The contrary is realized in some *V. faba minor* ssp. *paucijuga* types from the Hindukush region, showing small, 2 seeded pods with less than 0.3 g weight per seed, growing on small, gracile, tillering plants with very slender leaflets. These types are suspected to represent the most primitive version of *V. faba* (Cubero, 1974).

V. faba is one of the cytogenetically best characterized plants. Its six chromosome pairs contain as much as 1C approximately 13 pg (picogram) of DNA, which corresponds approximately to 13000 Mbp (mega base pair). The first, very large chromosome (about 18 μ m length) is metacentric, with one satellite. There are five similar (approx. 7–9 μ m length) acrocentric chromosomes (Figure 2). The metacentric chromosome I of *V. faba* probably originated from a remote fusion of two telocentric chromosomes. Many cytogenetic phenomena were observed for the first time by studying *V. faba*, for instance, nucleolus formation at the secondary constrictions during telophase, or the existence of an upper tolerance limit for chromosome arm length (Schubert and Oud, 1997; Fuchs *et al.*, 1998).

1.3 Economic Importance

At the worldwide scale, faba bean occupies about 2.6 millions ha, which in 2005 represented 4%

of the total area dedicated to pulses. From the worldwide area occupied by faba bean, 41% was concentrated in Asia, 33% in Africa, only 12% in Europe, and 7% in Oceania as well as in America. China is the largest grower of faba bean in the world with 39% of the worldwide area. In Africa, faba bean is mostly concentrated in Ethiopia (15% of the world wide faba bean area). The worldwide production in 2005 was about 5.8 million tons of which China produced 43% and is, therefore, the largest producer in the world (<http://faostat.fao.org/site/336/DesktopDefault.aspx?PageID=336>).

Faba bean is a very minor crop in Germany (16 000 ha in 2005), in Poland (12 000 ha), and Austria (4000 ha). France did grow a total of 105 000 ha, amounting to one third of the French pea acreage. In the United Kingdom, faba beans were grown in 188 000 ha, this is double the area grown to pea plus lupins. Spain had in 2005 about 53 000 ha of faba bean. Mediterranean types are sown in late autumn. In parts of the United Kingdom and France, where winter is relatively mild, autumn sowing of faba beans is to some extent practiced as well using “true” winter beans that can survive winters north of Pyrenees Mountains and Alps. In the United Kingdom, more or less, half of the faba beans are such winter types. All types of faba bean can survive very mild frosts as young plants (until about -6°C). Beans from the Hindukush do even show some frost tolerance in later stages. Autumn sowing is as well realized in North Africa, in southeast China (along the Yangtze Valley), and parts of Japan.

Cultivated faba bean is used as human food and as animal feed, mainly for pigs, horses, poultry, and pigeons in developing countries and almost strictly as animal feed in developed countries. For the human consumption, it can be used as a vegetable, either green or dried. Feeding value of faba bean is high; with about 30% of protein it is considered in some areas to be superior to field peas or other legumes. It is one of the most important winter crops for human consumption in the Middle East. Faba bean has been considered as a meat extender or substitute and as a skim milk substitute. Roasted seeds are eaten like peanuts in India. The proportion of the dried faba bean used as human food in the developing countries is not defined but data are available for green faba bean and allow assessing the contribution of faba bean

in the human nutrition. Its use as green vegetable amounts to 20% of the total production of faba bean. It is a common food in the Middle East, Mediterranean region, Latin America, China, and Ethiopia. The production of green faba bean in the Mediterranean region accounts for 40% of the worldwide green bean production. The Middle East and Latin America contribute equally with about 19% to the worldwide green bean production. Other uses of faba bean have been identified. Indeed, haulm from faba bean harvest fetches a premium in Egypt and Sudan and is considered as a cash crop. The haulm can also be used for brick making and as a fuel in parts of Sudan and Ethiopia (<http://faostat.fao.org>).

1.4 Traditional Breeding

The breeding objectives for this crop totally depend on the economic and agro-ecological conditions and on the geographical region and use. For combine harvest of dry, mature seeds, all pods and even stem and leaves of the crop have to become mature simultaneously, whereas for manual harvest of vegetable green bean pods, a long-lasting harvesting period is sought. For combine harvesting, nonshattering and nonlodging habits are essential, whereas they are of lesser importance for the production of green pods. For the production of feed, mostly small grains are bred, whereas for human consumption, equina and major types are preferred in most areas (except Ethiopia, where small types are used for food). Moreover, color, taste, and cooking features are important for vegetable type germplasm. If grown for animal feed, primarily mature grain yield and yield stability are sought, and to sustain high performance, resistance against drought (and winter frost in case of winter bean breeding) and against fungi, pathogens, and pests is needed. An additional objective is mature grain quality, depending on the actual animal species to be fed.

Normal faba beans show indeterminate growth; flowers and very young pods grow in competition with the vegetative apex of the stems. Several alternative growth types have been studied as a strategy to strengthen the pods as sinks for assimilates. The so-called *ti*-type (terminal inflorescence, or “topless”) and the so-called stable type (*st*, somewhat stunted habit, and very stiff stem) were

introduced. Dwarfism is known as well. These phenotypes are all caused by a single recessive allele (ICARDA, 1986). Several corresponding cultivars have been bred in Germany, like “Tina” (*ti*), “Tinova” (*ti*) or like “Boss” (*st*) and “Mythos” (*st*). Still, these are not widely used, and no such type is present on the 2005 German list of varieties. On the other hand, very recently, Nadal *et al.* (2005) in Spain proposed the use of the *ti*-type as a solution in broomrape-infested (see below) conditions (production of young pods for fresh consumption). There has been a remarkable input into a type named “independent vascular supply” (*ivs*). Gates *et al.* (1983) proposed to circumvent the physiological interaction and competition between pods and flowers within the same inflorescence by independent vascular traces to each flower, so that direct interaction between flowers and young pods cannot occur, and distinguished this type from the “usual” branched vascular pattern. The conclusion was that selection for *ivs* would be most reliable to improve pod set. By microscopic studies, Ruckenbauer and Mollenkopf (1983) found that a classification into independent and branched vascular bundles is not adequate. In material that was claimed to express the *ivs* features, these authors found no hints on any structural deviation of the vascular traces from “normal” beans.

Faba bean, in spite of its high importance in several semiarid regions like the Mediterranean Basin, is rather susceptible to drought. Its main mechanism to deal with this stress is a very early and sensitive stomata closure. Adapted material escapes terminal drought by earliness, whereas no powerful strategy is known to deal with unpredictable, intermittent drought. Several physiological traits may be used to assist in breeding for drought tolerance. Germplasm from gene banks like ICARDA was used to specifically enlarge diversity. Frost resistance is mostly analyzed as a component of winter survival. Very few genotypes with outstanding frost resistance are known (Stoddard *et al.*, 2006). Similar to drought, physiological traits might help in breeding, such as fatty acid composition of leaves (Arbaoui and Link, 2006). No molecular tools are as yet available in faba bean breeding for these two traits.

The most important fungal foliar diseases are *Botrytis fabae*, *Ascochyta fabae*, and *Uromyces viciae-fabae*; besides, root rot caused by *Rhizoctonia solani*, *Fusarium* species, and other fungi can

occur. *Botrytis* is seen in a wide range of growing conditions, it is often a very serious threat, and still no convincing source of resistance is known. Severe outbreaks are most common in the Nile delta, near rivers in China, rainy coastal areas of the Mediterranean Basin, and the more oceanic climate of western France and western United Kingdom (Tivoli *et al.*, 2006). Differences in susceptibility follow a quantitative genetic pattern. Several less susceptible bean genotypes are known (e.g., some ICARDA lines originating from South America). For *Ascochyta* and *Uromyces*, specific resistances are known and even molecular markers were developed. The line 29H, amongst others, was repeatedly used to improve *Ascochyta* resistance. Bean rust (*Uromyces*) resistance is available in many cultivars. Qualitative resistance is common and widely used by breeders (Sillero *et al.*, 2006). *Phoma* and mildew cause further less well-studied foliar diseases in *V. faba*. Few, if any, convincing sources of resistance against root rot are known. Material with a zero content of tannin (see below) in the seed testa (monogenic recessive feature) seems to be more susceptible at germinating and emergence than tannin-containing germplasm.

Viruses are not a frequent problem for the faba bean producer; still, viral diseases may occur as serious epidemic. The bean yellow mosaic virus, bean leaf roll virus, broad bean true mosaic virus, and the broad bean stain virus must be named. Since no direct pesticide protection exists, the genetic strategy must hold. The two latter viruses are to some extent seed transmitted and not aphid transmitted. Yet, the beetle *Sitona lineatus* (see below) spread these two viruses early in the season (Rohloff, 1980). There has been promising breeding research prior to 1989 in GDR, but these programs were then abandoned (Lötsch, 1989). In 1992 and again in 1999, a new, aphid-transmitted virus (faba bean necrotic yellow virus) occurred at a devastating level in the Nile Valley. Meanwhile resistant genotypes have been identified (e.g., “ILB132” Khaled *et al.*, 2000).

The most important pest is *Aphis fabae*, the black aphid. It occurs very often at significant levels, therefore, insecticides are used. In addition to the direct damage, it is spreading viruses. No useful resistance is known. Even earlier in the season than this aphid, the weevil *S. lineatus* feeds on the first, very young leaves. More important is the damage of its larvae, which feed on the

root nodules and thus cause direct damage and probably increase root rot (Salt, 1983). *Bruchus rufimanus*, a seed-infesting weevil, is present in most faba bean fields and stocks. The female deposits the eggs in the field onto the very young pods. Infested seeds are not accepted for human consumption, thus the beetle is a serious threat for this aspect of production. Additional *Bruchus* and *Callosobruchus* species live in bean seeds (mainly in the Middle East); several of them complete their cycle in the store, the female laying the eggs onto the testa of mature dry seeds. The dry seed coat is a barrier, and not all the larvae can enter and overcome it; there is no connection to the seed coat's tannin content. The present breeding of new cultivars with reduced vicine and convicine content (see below) of the seed can favor the colonization of faba bean by additional weevils such as *Callosobruchus maculatus* that does not infest normal-vicine faba beans (Desroches *et al.*, 1995).

In addition to aphids and beetles, nematodes have to be mentioned. Faba bean may be infested by the stem nematode (*Ditylenchus dipsaci*) and the cyst nematode (*Heterodera goettingiana*). The stem nematode is widespread, and its "giant" race, common in North Africa, is a serious pest, especially in cases where nematode-infested seeds are sown. Small-seeded beans are generally a poorer host, several resistant genotypes were identified, amongst them is the *Ascochyta* resistant line 29H. The cyst nematode is important in many temperate regions. Obviously no resistances have been found (Sharma *et al.*, 1994). Broomrape, *Orobanche crenata*, is a parasitic plant, devastating pulses and other crops in the Mediterranean Basin and Nile Valley. Hand weeding, use of glyphosate, late sowing and breeding is used to fight it. Breeders have up to now not produced a bean with reliable resistance. Screening is mostly done in fields where this parasitic weed occurs naturally, which is a difficult test situation. Evaluations in controlled environments are possible but expensive. These shortcomings make broomrape resistance a problematic trait. Partially resistant genotypes are available; the resistance trait shows a quantitative genetic variation. The rather resistant genotype F402 identified by Egyptians was repeatedly used. Several improved genotypes have been bred from this common source in Egypt ("Giza 402", "Giza 429", "Giza 674")

and in Spain ("Vf1071", "Vf136", "Baraca"). Meanwhile, three quantitative trait loci (QTLs) for resistance were identified (Torres *et al.*, 2006). *Orobanche* resistance is a trait that shows all features to make it a candidate for marker-assisted selection. It is a very serious problem, resistance shows quantitative genetic variation, difficult to phenotype the trait, and there is only one unique, common source of resistance ("F402"). Up to now, the level of cooperation among breeders and scientists in the Mediterranean Basin and Nile Valley is scanty to realize the importance of this pest and to employ modern breeding techniques.

Breeding for improved quality aims mainly at increase of the seed protein content and protein quality. Protein content could easily be increased to over 30%. Still, as long as there is no economic incentive to do so, breeders will not invest significant effort in achieving this goal. Protein quality is mainly limited due to a low sulfur-containing amino acids such as methionine and cysteine. Classical methods are not promising, since the variation is low and there is a negative genetic correlation between seed protein content and sulfur-containing amino acids' content of this protein (Link *et al.*, 2005). Quality, moreover, depends on the content of antinutritional factors like condensed tannins and vicine. Zero-tannin cultivars, for example those for feeding pigs, do exist (e.g., "Gloria"). The recessive monogenetic segregation of this gene and the pure white flower, as its pleiotropic effect, make this trait easy to handle. Low vicine cultivars do as well exist (e.g., "Mélodie"). The trait is again monogenetic recessive, a morphological marker (white hilum) and even molecular markers are available. Vicine may have negative effects on human health. A rare human enzyme deficiency, favism, leads to anemia upon faba bean consumption in affected individuals. Also, vicine negatively effects monogastric animal nutrition like pigs and chicken. Further antinutritional compounds are not of importance in faba beans (Duc *et al.*, 1999).

Classical breeding in faba bean looks back on very marked improvements, e.g., for non-shattering, improved yield and yield stability, highly improved lodging resistance. Still, breeding progress is hampered by the partial allogamy of the bean. The pollinators are bumble bees and honey bees (Link *et al.*, 1994a; Suso and Moreno, 1999). The degree of cross-fertilization is about 50%, with

Figure 3 Theoretical distribution of individual plant's performances in case of partially allogamy like in faba bean, here with 50% outcrossing of inbred plants and 30% outcrossing of noninbred plants. The population is shown as composition of cohorts of plants with different levels of inbreeding [Reproduced from Link *et al.* (1994b)]

a large genotypic and environmental component of variation and with marked heterosis; heterozygous plants show on average less outcrossing than homozygous plants. Inbreeding depression for grain yield is marked; F_1 -hybrids outyield their inbred parents mostly by more than 40%. The partial allogamy and the marked heterosis for vigor and productivity cause the genetic variation of a faba bean population to be very much inflated (Figure 3), compared to a situation of pure selfing or pure outcrossing. This reduces markedly the gain from mass selection for these traits. The reason is that the superiority of the selected plants is mainly caused by their high heterozygosity, not by a high breeding value; heterozygosity, however, is not inherited. A solution is to strictly select among entries of identical level of inbreeding, preferentially among pure lines.

The first approaches to realize the production of hybrid cultivars (based on cytoplasmic-genetic male sterility) in faba bean trace back to Bond in Cambridge in 1957 and to Berthelem in Rennes in 1967. Bond worked with the system CMS447, discovered by him in winter beans in Newcastle upon Tyne. Berthelem discovered the system CMS350 in an English bean population. The system CMS350 was found to be sensitive to environmental conditions. The system CMS447

is very peculiar, since a genetic restoration of pollen fertility becomes permanent; offspring that segregates from a heterozygously restored plant does not segregate for the pollen sterility as expected from textbook schemes on cytoplasmic male sterility (CMS) systems. Molecular genetic findings proposed that CMS447 may be the result of an infection with a defect virus, and that restoration corresponds to nontransmittance by seeds (Pfeiffer *et al.*, 1993). In Germany, Link *et al.* (1997) detected two other CMS systems (CMS199, CMS297), yet due to instability of the sterility, especially due to spontaneous reversions to pollen fertility, hybrid breeding still could not be realized in faba bean.

As classical breeding category, line breeding is applied. An important bottleneck in line breeding is the production of purely selfed seed. In the open field situation of a breeding nursery, with small plots and large numbers of genotypes, seed multiplication suffers from uncontrolled contamination with cross-pollen, unless spatial isolation and pure lines are used. In cages, pollinators can be excluded and pure self-fertilization can be enforced. Still, without pollinator visit, most genotypes admit a need of tripping (a mechanical stimulation of the stigma, caused by the pollinator, which induces successful pollination and fertilization). As a consequence of absence of pollinators, yield of purely selfed seed in cages is variable and mostly very low. Germplasm from Southern Europe and Northern Africa often shows a lower or no need of tripping. Tripping can be done manually, to substitute for the missing pollinators in the cages, thereby allowing true selfing and high seed set, but this is a very labor-intensive procedure. A very successful alternative to pure inbred line cultivars is the breeding of synthetic cultivars. Still, due to the limited degree of natural outcrossing, only about half of the potential hybrid vigor is used in a synthetic cultivar.

1.5 Rationale for Transgenic Breeding

The development of gene transfer techniques for faba bean is of commercial interest as they might facilitate the production of cultivars with improved characteristics, such as resistance to biotic and abiotic stresses and enhancing the nutritional value. Chocolate spot, caused by *B.*

fabae and *Ascochyta* blight, caused by *A. fabae* are the most widespread and devastating fungal diseases in all production areas. Viral diseases and the parasitic weed broomrape (*O. crenata*) are the most important factors contributing to the losses in faba bean production in the West Asia North Africa (WANA) region (Hanounik *et al.*, 1993; Robertson and Saxena, 1993). Losses in faba bean caused by broomrape are estimated at the range from 50% to 80% in fields with medium and high levels of infestations, respectively (Gressel *et al.*, 2004). Pests like black bean aphid (*A. fabae*), sitona weevil (*S. lineatus*), stem nematode (*Ditylenchus dipsaci*), and bruchid beetle (*B. rufimanus*) also limit the yields, if no pest control is employed. Abiotic stresses like cold and drought are also major constraints to yield as strong tolerance genes are not available in the primary gene pool of *V. faba*. These constraints are strong arguments for genetic transformation for the improvement of this crop. Recombinant DNA technology if applied to faba bean, however, requires the development of efficient and reproducible protocols for both regeneration and genetic transformation. The combination of conventional breeding approaches, plant tissue culture techniques, and recombinant DNA technology will open the necessary avenues needed for improvement of faba bean in overseeable time.

2. DEVELOPMENT OF TRANSGENIC FABA BEANS

Faba bean exhibits a rather low competence for *in vitro* culture. This is mainly due to the difficulties in the regeneration from callus tissues and the high content of phenolic compounds, which causes cell death if not overcome (Bieri *et al.*, 1984; Selva *et al.*, 1989). Unfortunately, efficient *in vitro* techniques are limited for faba bean as compared to other major economically important crops. Faba bean genetic transformation continues to be problematic even with the intense efforts of the researchers in this field. As a consequence, among the major grain legume crops *V. faba* was the last species where the production of transgenic plants had been reported (Böttinger *et al.*, 2001; Hanafy *et al.*, 2005). In contrast, the closely related species *V. narbonensis* could be relatively easy to be manipulated *in vitro* (Pickardt *et al.*, 1991).

Several investigators worked extensively on faba bean transformation and regeneration of transgenic plants in the past (Schiemann and Eisenreich, 1989; Ramsay and Kumar, 1990; Saalbach *et al.*, 1994; Siefkes-Boer *et al.*, 1995; Jelenic *et al.*, 2000). The first attempts to transfer foreign genes into faba bean were published by Schiemann and Eisenreich (1989). They used *Agrobacterium rhizogenes* containing the binary vector pGSGluc1 carrying *nptII* and *uidA* genes under the control of the bidirectional TR1/2 promoter. β -glucuronidase (GUS)-positive roots and subsequently transgenic calli lines were obtained. A similar study was performed by Ramsay and Kumar (1990), using an *A. rhizogenes* strain containing pBin19 for inoculation of *V. faba* cotyledons and stem tissue, leading to successful transfer of the *nptII* marker gene. However, no transgenic faba bean plants were regenerated in any of these studies. Since the lack of efficient protocol for regeneration of transgenic plants was the main obstacle in faba bean transformation, Jelenic *et al.* (2000) tried to solve this problem by application of bacteria carrying shooty types Ti-plasmids, pGV2215, and pGV2235. Neither of the two mutants appeared to be useful for faba bean regeneration.

Finally, Böttinger *et al.* (2001) recovered the first transgenic faba bean plants from transformed tissues. Their system was based on *de novo* regeneration using thidiazuron (TDZ). The second successful protocol developed by Hanafy *et al.* (2005) was based on direct shoot organogenesis from meristematic cells of mature or immature embryo axes.

2.1 *Agrobacterium*-mediated Transformation and Regeneration of Transgenic Faba Bean Plants

Böttinger *et al.* (2001) reported, for the first time, a method for the production of transgenic faba bean plants. This *Agrobacterium*-mediated transformation protocol, adopted from a plant regeneration protocol for protoplast derived calli (Tegeder *et al.*, 1995), was based on the *de novo* regeneration of shoot initials from callus. The transgenic plants were recovered by inoculation of stem segments with *Agrobacterium* strains EHA 101 or EHA 105, harboring different binary vectors (Table 1). Calli were induced on MS medium (Murashige

Table 1 Summary of successful transgenic faba bean production strategies

Cultivar	Explant	<i>A. tumefaciens</i>	Transgene	Selection	References
Mythos	Etiolated epicotyls	EHA 101, EHA 105	<i>uidA</i> , <i>nptII</i> , <i>bar</i> , <i>sfa8</i> , <i>lysC</i>	Kanamycin, phosphinothricin	Böttinger <i>et al.</i> , 2001

and Skoog, 1962) containing 0.5 mg l^{-1} of each TDZ, 2,4-dichlorophenoxyacetic (2,4-D), and naphthylacetic acid (NAA) and 100 mg l^{-1} kanamycin or 2 mg l^{-1} DL-Phosphinothricin (PPT) as a selective agent. Afterwards, transgenic shoots were regenerated *via* organogenesis using a high concentration of TDZ (7.5 mg l^{-1}) and 0.75 mg l^{-1} NAA. Finally, plants were recovered by micrografting. The process required 16–24 months to get seed-producing primary transformants. It was laborious and time consuming because the quantum of regenerable tissue was very limited and it had relatively low regeneration efficiency, prone to somaclonal variation.

Consequently, in an effort to improve the transformation efficiency of *V. faba* and to overcome the difficulties reported by Böttinger *et al.* (2001), an *Agrobacterium*-mediated transformation system based upon direct shoot organogenesis has been developed (Hanafy *et al.*, 2005). After transformation of meristematic cells derived from zygotic embryo axes stable and fertile transgenic plants were regenerated. The use of

embryonic axes, which were cultivated on media containing high concentrations of cytokinins in combination with low auxin, enhanced direct shooting without an intermediate callus phase. In this manner the possibility of somaclonal variation has been reduced to the minimum. This transformation system was an adaptation of the protocol previously reported by Schroeder *et al.* (1993) in *P. sativum*. It allowed obtaining seed-bearing primary transformants within approximately 9–10 months (Hanafy *et al.*, 2005).

2.1.1 Faba bean cultivars and *A. tumefaciens* strains

Successful transformation and regeneration of transgenic faba bean plants has been achieved with three cultivars so far: *Mythos*, *Albatross*, and *Giza 2*. Growth media used for tissue culture, transformation, and regeneration are listed in Table 2. Mature faba bean seeds were surface sterilized (ethanol and sodium hypochlorite solution),

Table 2 Growth media used for the production of transgenic faba bean plants

Media	Composition ^(b)
TNZ	MS + 3% sucrose, 0.5 mg l^{-1} 2,4-D, 0.5 mg l^{-1} NAA, 0.5 mg l^{-1} TDZ
TNZ1	MS + 3% sucrose, 0.5 mg l^{-1} 2,4-D, 0.5 mg l^{-1} NAA, 0.5 mg l^{-1} TDZ, 500 mg l^{-1} Betabactyl
TNZ2K	MS + 3% sucrose, 0.5 mg l^{-1} 2,4-D, 0.5 mg l^{-1} NAA, 0.5 mg l^{-1} TDZ, 300 mg l^{-1} Betabactyl, 100 mg l^{-1} kanamycin
TNZ2P	MS + 3% sucrose, 0.5 mg l^{-1} 2,4-D, 0.5 mg l^{-1} NAA, 0.5 mg l^{-1} TDZ, 300 mg l^{-1} Betabactyl, 2 mg l^{-1} PPT
MTN	MS + 3% sucrose, 7.5 mg l^{-1} TDZ, 0.75 mg l^{-1} NAA
MB1	MS + 3% sucrose, 1 mg l^{-1} BAP, 1 mg l^{-1} GA3, 100 mg l^{-1} coconut milk, 100 mg l^{-1} Ticarcillin, and 50 mg l^{-1} Combactam
CCM	Gamborg B ₅ medium + 3% sucrose, 0.5 mg l^{-1} kinetin, 1 mg l^{-1} 2, 4-D
SRM	MS basal salt medium supplemented with B ₅ vitamins ^(a) + 3% sucrose, 2 mg l^{-1} NAA, 2 mg l^{-1} BAP, 150 mg l^{-1} Ticarcillin, and 100 mg l^{-1} Combactam
SIM1	MS basal salt medium supplemented with B ₅ vitamins + 3% sucrose, 4.5 mg l^{-1} BAP, and 2 mg l^{-1} PPT
SIM	MS basal salt medium supplemented with B ₅ vitamins + 3% sucrose, 4.5 mg l^{-1} BAP, 0.1 mg l^{-1} NAA, 100 mg l^{-1} Ticarcillin, 50 mg l^{-1} Combactam, and 2 mg l^{-1} PPT

^(b)Antibiotics and phosphinothricin are added to the medium after autoclaving. Cultures are kept at 21°C under cool white fluorescent light ($80 \mu\text{mol m}^{-2} \text{ s}^{-1}$)

soaked overnight in sterile tap water with shaking and germinated in the dark at 20 °C on $\frac{1}{2}$ MS-basal medium. After about 10 days, internodal segments of the arising main shoots were used for co-cultivation with *Agrobacterium tumefaciens*. The remaining seedlings were kept in dark, and secondary shoots, arising from the cotyledonary buds during the following weeks, were used as explants source for further transformation experiment.

The following *A. tumefaciens* strains have been successfully used for production of transgenic faba bean plants (Böttinger *et al.*, 2001; Hanafy *et al.*, 2005): (1) EHA101 carrying pGSGluc1, harboring *uidA* and *nptII* genes, both under the control of the bidirectional TR1/2 promoter; (2) EHA101 carrying pAN109, harboring the *nptII* marker gene under the nopaline synthase promoter (*Pnos*) and the mutated *Escherichia coli lysC* gene, coding for a feed-back desensitized aspartate kinase III (Shaul and Galili, 1992), driven by the seed specific bean phaseolin promoter; (3) EHA105 carrying pBIOU, harboring the *Pnos-nptII* marker cassette and an intron-containing genomic sequence for the sunflower 2S-albumin 8 (*sfa8*; Kortt *et al.*, 1991), driven by the seed specific *usp* promoter from *V. faba* (Bieri *et al.*, 1984); (4) EHA105 carrying pGlsfa (pGPTV-bar derivative, Becker *et al.*, 1992), harboring the *sfa8* gene under the seed specific legumin B promoter (LeB4) and the *bar* gene under the *nos* promoter.

Bacteria carrying the desirable vector were harvested by centrifugation and resuspended in an equal volume of liquid TNZ medium (*de novo* regeneration protocol) or the bacterial culture was diluted in a rate of 1:5 with liquid CCM (embryo axes transformation system). Etiolated epicotyls were cut into segments of 0.2–0.4 cm in length in the bacterial suspension and incubated for 30 min, then transferred into 250 ml glass containers with solidified TNZ medium and co-cultivated for 48 h at 20 °C in the dark (*de novo* regeneration protocol).

Regarding the embryo axes transformation system, embryo axes of both mature and immature seeds were wounded by the removal of the root tips and slicing of the embryo axes to three or four segments longitudinally and inoculated in the bacterial suspension for 15–20 min (immature embryos) and 30 min (mature embryos) with occasional agitation. After infection, the explants (30–40 per plate) were co-cultivated on solid

CCM medium at 25 °C in dark for 3–4 days. After the co-cultivation period, explants were cultured in a glass container on TNZ1 medium, in the dark at 20 °C for 3–4 days, for recovering without selection pressure. The explants were subsequently transferred to TNZ2K- or TNZ2P-medium (depending on the selectable marker). The explants were subcultured every 2 weeks on fresh medium for a period of 3–4 months. Resistant calli reaching a diameter of approximately 5 mm were transferred to MTN-medium. Calli were subcultured every 3–4 weeks on this medium for a period of more than 12 months. The appearance of shoot primordia varied between 4 and 12 months. Shoot primordia were transferred to elongation medium (MB1) and subcultured every 3–4 weeks.

Healthy resistant shoots, more than 1 cm in length were excised and grafted onto etiolated seedlings of untransformed faba bean of about 7–10-day-old (see Pickardt *et al.*, 1991 for details). After 2–3 weeks, when the shoot developed new leaves, the transgenic plants were transferred to the greenhouse and grown to maturity.

2.1.2 Transgenic faba bean plants

Two successful protocols for regeneration of transgenic faba bean plants have been developed so far. The first protocol was based on *de novo* regeneration using TDZ (Böttinger *et al.*, 2001), and the second protocol was based on direct shoot organogenesis from meristematic cells of mature or immature embryo axes (Hanafy *et al.*, 2005). In both these transformation systems, the control experiments showed that PPT at 2 mg l⁻¹ totally suppressed callus development from wild type faba bean epicotyl segments, cultured on TNZ, or embryo axes cultured on shoot inducing medium (SIM1).

With regard to the *de novo* regeneration protocol, in a series of transformation experiments, resistant callus started proliferating after about 1–2 months on the surface of a number of explants on TNZ2P medium. Within 3–4 months after culturing the explants on TNZ2P medium, 4.3–31.6% of the explants produced resistant calli (Figure 4). PPT resistant calli with a diameter of about 5–10 mm were transferred to the MTN medium to increase the callus viability

Figure 4 Successful transformation and regeneration of transgenic faba bean. (a) Initiation of resistant callus from stem explants under selection pressure of 2 mg l^{-1} PPT on TNZ2P- medium. (b) Callus proliferation on MTN medium. (c) Shoot regeneration on MTN medium. (d) Explant segments derived from embryonic axes. (e) Multiple shoot regeneration under selection pressure (left), all the control explants (WT) were dead (right). (f) Further selection between PPT resistant and susceptible regenerated shoots on medium containing 2 mg l^{-1} PPT. (g) Recovering the transgenic plant by micrografting

to regenerate (Figure 4). Shoot regeneration occurred after 6–12 months on MTN medium (Figure 4c). Shoot primordia were transferred to shoot elongation medium, MB1. Because of the very low rooting percentage of the regenerants, shoots reaching a suitable size (within 2–4 months) were micrografted onto nontransgenic root stocks of faba bean to recover whole plants. Afterwards, the plants were transferred to soil for acclimatization. Regenerated plants were transferred to the greenhouse for further plant development and production of T_1 seeds. Some regenerated clones showed morphological abnormalities, such as dwarfness and formation of abnormal flowers and subsequently abnormal (or no) pods. Some plants showed narrow leaves and very weak stems with weak apical dominance. Only four clones of the cultivars Mytos and Giza 2 produced normal flowers and pods with seeds. The time needed to obtain T_1 seeds by this process was about 16–24 months.

On the other hand, the feasibility of the transformation strategy based on embryo axis transformation was initially evaluated by monitoring the number of regenerated shoots from the embryo axis explants, cultured on medium with high 6-benzylaminopurine (BAP) concentration (4.5 mg l^{-1}), where routinely 4–5 shoots were regenerated from each explant. In a series of transformation experiments, the explants (immature or mature embryonic axes) were inoculated with

Agrobacterium strain EHA105/pGlsfa (harboring *SFA8* and *bar* genes) alone, or co-transformed with EHA101/pAN109, which carried a mutated *lysC* gene from *E. coli* and *nptII* (Böttinger *et al.*, 2001) (Figure 4d). After 3–4 weeks of culturing on selective medium, all control explants had died. On the other hand, the transformed explants started regenerating (via organogenesis), and about 3–4 shoots appeared from each explant on SIM (Figure 4e). The shoots selected for 4–6 months (Figure 4f) were grafted *in vitro* and finally transferred to the greenhouse to set seeds (T_1) (Figure 4g). A total of seven stable independent transformants (containing *SFA8* linked to *bar* from cv. Mytos and Albatross) have been recovered. Transformation frequencies ranged from 0.15% to 2.0%. Regarding the co-transformation experiments, transformed plants (T_1) were screened for the presence of both transfer DNAs (T-DNAs) by PCR analysis. It was found that only the T-DNA encoding the PPT selectable marker has been successfully integrated. The time needed to obtain T_1 seeds by this protocol was about 9–10 months.

The transgenic plants were analyzed by testing the expression of *bar* gene in the greenhouse by using the leaf painting assay or spraying the young plants with the same dilution of the herbicide. Within two days necrotic spots appeared on the untransformed leaves. Ten days after BASTA[®] (phosphinotrycin glufosinate

Figure 5 Herbicide leaf painting test showing the resistance of transgenic leaf to BASTA[®] (300–400 mg l⁻¹ ammonium glufosinate) application (left)

ammonium) application, the treated transgenic plants and leaflets showed complete tolerance, in contrast to completely necrotic leaflets on nontransformed plants (Figure 5).

3. FUTURE ROAD MAP

Each of the two successful protocols for regeneration of faba bean transgenic plants (Böttinger *et al.*, 2001; Hanafy *et al.*, 2005) has its advantages and drawbacks.

The major advantage in using *de novo* regeneration protocol is regeneration of nonchimeric plants. This process, however, is more time consuming and the main constraints in this protocol are poor regeneration ability, following a callus phase, reduced fertility and high percentage of phenotypic abnormalities in regenerated plants. This can be ascribed to the fact that explants and callus cells of *V. faba* tend to produce high amounts of phenolic compounds, resulting in subsequent intoxication of the tissue (Bieri *et al.*, 1984; Selva *et al.*, 1989). A possible cause of these abnormalities is also due to the long culture time *in vitro* (around 7–16 months). The recovery of seed-producing putative transformed plants under these circumstances takes about 16–24 months, which is a considerably long time period. Transformation strategies, which minimize the *in vitro* culture

period and avoid the callus phase would, therefore, be advantageous.

Transformation of pre-excited meristematic cells on the embryo axes is much simpler. The major success in legume transformation was achieved by methods based on transformation of the pre-existing meristems on the embryo axes, cotyledonary nodes, shoot tips, or nodal explants. An *Agrobacterium*-mediated genetic transformation system using pre-excited meristematic cells on the embryo axes is an effective method for the production of transgenic faba bean, which provides a useful strategy for an efficient insertion of the economically useful genes into its cultivars. It was demonstrated that the embryo axes of faba bean are competent for production and multiplication of shoots and inherited transformation.

The production of commercial transgenic faba bean plants requires an efficient regeneration system. Although transgenic faba bean plants can now be regenerated successfully, the process is still labor-intensive and therefore, requires improvement.

3.1 Expected Products

Some of the problems of classical faba bean breeding might be addressed by applying strategies of genetic modification. *Orobanche* sp. was shown to be sensitive to glyphosate (Lolas,

1994; Goldwasser *et al.*, 2002). In this respect, it would be feasible to introduce genes conferring resistance to glyphosate to faba bean, like 5-enolpyruvylshikimate-3-phosphate synthase from the CP4 strain of *A. tumefaciens* or glyphosate oxidase from *Ochrobactrum anthropi*. These genes are already being efficiently used in commercial transgenic crops like cotton and soybeans (Padgett *et al.*, 1995; Saroha *et al.*, 1998). BASTA (phosphinotrycin-glufosinate ammonium) or bromoxilin herbicide resistance genes could be introduced as well (Cubero and Nadal, 2005). They are not effective against *Orobanche* sp., but could be of help against other unwanted weeds in the field. Similarly, insect pests of faba bean from the orders *Lepidoptera*, *Coleoptera*, and *Diptera* could be controlled by heterologous expression of the Cry proteins from *Bacillus thuringiensis* (Schnepf *et al.*, 1998). Moreover, to reduce losses caused by aphids the *Galanthus nivalis* agglutinin (GNA), a lectin, might be tested in addition to Cry proteins (Wang *et al.*, 2005).

Nematode resistance could be conferred to faba bean by the introduction of the *Mi-1.2* gene from the wild relative of tomato *Lycopersicon peruvianum*. It was shown that this gene contributes resistance against nematodes, but also against aphids, when introduced to cultivated tomato (Rossi *et al.*, 1998). Heterologous expression of the same gene in eggplant (*Solanum melongena*) displayed resistance to nematodes (Goggin *et al.*, 2006). A comprehensive list of other cloned or mapped nematode resistance genes from different species has been published recently (Williamson and Kumar, 2006).

The problem of faba bean fungal diseases could potentially be solved by transformation with genes encoding for plant defensins, a group of small peptides broadly present throughout the plant kingdom. These peptides exhibit a wide-range antifungal activity, when expressed heterologously (Thomma *et al.*, 2002). For example, the *Alium cepa* antimicrobial protein 1 (*Ace-AMP1*; Cammue *et al.*, 1995), a defensin, was shown to be very efficient in conferring *Batrachyomyces* resistance to *Pelargonium* sp. (Bi *et al.*, 1999), powdery mildew resistance to *Rosa hybrida* (Li *et al.*, 2003), and most recently, conferring resistance to several fungal pathogens in wheat (Roy-Barman *et al.*, 2006).

The only two reports so far, describing successful regeneration of transgenic faba bean, raise hope

of the feasibility of nutritional value improvement by transgenic approaches. Böttlinger *et al.* (2001) demonstrated the expression and specific activity of the mutated *lysC* gene in transgenic faba bean plants. Still, the desired change in amino acid composition in the transgenic seeds remains to be demonstrated. In addition, the same group demonstrated the expression of the methionine-rich sunflower albumin gene *sfa8* in faba bean transgenic lines using RT-PCR. However, due to the lack of the specific antibody, it was not possible to demonstrate the accumulation of the corresponding protein in the generated lines. The work of Hanafy *et al.* (2005) made another important step forward. By RT-PCR the authors detected the presence of the *sfa8* transcripts in the T₂ and T₃ generation of their transgenic lines. More importantly, by Western blot analysis the accumulation of the SFA8 protein was demonstrated in transgenic faba bean lines. In the two tested generations (T₂ and T₃), the *SFA8* expression level remained uniform. The exact levels of the foreign protein could not be determined, due to the lack of purified *SFA8*.

Apart from demonstrating that the transgenic approach could be used to improve protein quality in faba bean, these two reports also showed that the *bar* gene (PPT acetyltransferase) could be effectively used as a selective agent of transgenic individuals, instead the unpopular antibiotic resistance. Phosphinotrycin resistance conferred by the *bar* gene, can be used in the early phase of positive clone selection. More importantly, *bar*-based selection is easily conducted in the glasshouse or in the field on fully grown plants.

3.2 Expected Technologies

The introduction of molecular biology techniques revolutionized plant research. In particular, the sequencing of the *Arabidopsis thaliana* genome has produced a wealth of information on virtually every aspect of plant biology. Also, it has set new standards that transformed the way plant research is done: high throughput mutagenesis, genome saturated collections of mutants, construction of dense genetic maps used in positional (map-based) cloning, excellent efficiency of *in planta* transformation, and availability of the whole-genome microarrays. However, *A. thaliana* simply

cannot encompass all the diversity of physiological processes present throughout the plant kingdom, e.g., the nodule development in legumes. Therefore, the development of legume-specific plant models is necessary. Today, two cool-season legume models are established: *Lotus japonicus* and *Medicago truncatula*. Similarly, *Glycine max*, as the economically the most important legume, is the model for the warm-season legumes. The complete genome sequences of the two cold-season model plants should be complete within the next 1–2 years (Young *et al.*, 2005). The soybean genome, due to its size of 1200 Mb, is relatively far from being completely sequenced.

Translating the knowledge gained through these model species, to crop legumes, such as *V. faba*, might improve both classical and transgenic breeding programs. Its 13 059 Mb genome (Zhu *et al.*, 2005) and its rather secondary economic importance, are serious obstacles for sequencing the faba bean genome. So, it is certain that faba bean breeders will have to rely on information extractable from sequences of the model legumes, at least for time being.

Genomics of model legumes represents the basis for understanding the molecular, as well as metabolic basis of synthesis and accumulation of desired compounds (e.g., storage proteins), and to decipher mechanisms by which legumes resist pests and unfavorable environmental conditions. Not less important, genomics is the base for generating large numbers of molecular markers that can be used to assist classical plant breeding.

The legume community has the intention to develop several translational genomic tools that will facilitate the exchange of genetic sequence information among different legume species. These “translational tools” include collections of expressed sequence tags (ESTs), complementary DNA (cDNA) libraries from different plant tissues (seed, leaf, nodule, flower, pod), as well as from various environmental conditions, genomic libraries, and generation of dense genetic maps. Due to limited resources, a priority list of legume species was defined. Faba bean is positioned reasonably high on that list, but only after common bean, chickpea, peanut, and peas (Gepts *et al.*, 2005). Eventually, sequencing of gene-rich regions for this group of crop legumes is planned. In addition, it is aimed to produce a set of at least 500 genetic markers per legume crop species, which

will be linked to whole-genome sequences of model legumes. In order to localize QTLs, such as for yield or seed protein composition, segregating populations for mapping agronomically important traits will be made available. The Legume Crops Genome Initiative (LCGI) predicted that within the next decade the complete *Phaseolus* sp. and *Arachis* sp. sequences will be ready, as well as partial sequences of *Pisum* sp. and *Cicer* sp. (Gepts *et al.*, 2005). At the moment, it is hard to predict whether *V. faba* will reach the same level of sequence information by that time.

For the model species *L. japonicus* and *M. truncatula*, more effort will be put on elucidating their transcriptome, proteome, and metabolome (Colebatch *et al.*, 2004). These datasets are inevitable to fully comprehend the regulation of synthesis of desired products: proteins, lipids, and carbohydrates, as well as secondary metabolites interacting with pathogens, symbionts, as well as beneficial or harmful insects.

As the amount of genomic sequences from both, the model and crop legumes, will grow, the correct annotation of gene function is going to be crucial. To perform functional annotation, reverse genetics approaches similar to those in *A. thaliana* are also being employed in model legumes, e.g., a TILLING facility (targeted induced local lesions in genomes; Till *et al.*, 2003) has been set up with about 5000 *L. japonicus* mutagenized lines (Gilchrist and Haughn, 2005).

The relatively close phylogenetic relationship of faba bean and the model legumes is a strong argument in favor of translational genetic strategies. This was further substantiated by one recent phylogenetic analysis of legumes, based on chloroplast maturase K (matK) sequence (Cronk *et al.*, 2006). In particular, the *Papilionoideae* subfamily, to which crop and model legumes belong, was subdivided into seven informally named clades. Faba bean was classified to the *inverted repeat loss clade* (IRLC), together with legume model *M. truncatula* and crop legumes *L. culinaris*, *P. sativum*, *Cicer arietinum*. The next most related clade *Robinioids* includes the other model legume *L. japonicus*.

The close phylogenetic relationship between faba bean and model legumes implicates the existence of common genomic microstructure and macrostructure. Macrostructural similarity, also referred as synteny implies the presence of the same genes on the same chromosome of two species. On

the other hand, microstructural similarity, referred as microsynteny or colinearity, indicates conserved gene order on a particular chromosome of two species. For example, it was demonstrated that *L. japonicus* and *M. truncatula* are structurally more conserved than, e.g., *Glycine max* and *M. truncatula* (Choi *et al.*, 2004). This is of practical importance for designing strategies for small scale sequencing projects and comparative mapping on faba bean. Another study compared conserved microsynteny between *G. max* and *M. truncatula*, using a hybridization-based approach (Yan *et al.*, 2003). The high degree of microsynteny detected in this study, implied that it should be possible to use the genome sequence of *M. truncatula* as a reference for isolating genes in soybean and other closely related legumes, e.g., faba bean.

A further example for using sequence information gained on model legumes in crop legumes is the cross-species application of EST- and genomic-derived SSRs (microsatellites) for *M. truncatula* in most important European legume pulses: pea, faba bean, and chick pea (Gutierrez *et al.*, 2005). Of 242 *M. truncatula* simple sequence repeats (SSRs) analyzed, approximately 40% gave cross-amplification in faba bean. Detailed sequence analysis of these SSR sequences showed a rather high variability in the microsatellite motif itself, and much more conserved flanking regions. However, amplified microsatellites did not show a size polymorphism in different parental genotypes of faba bean used in the study. This outcome sets limits to their use in mapping projects. Still, the effort to produce a large number of cross-legume markers will continue.

The germplasm of elite faba bean cultivars was reported to have a rather broad genetic base, as demonstrated by a recent amplified fragment length polymorphism (AFLP) analysis (Zeid *et al.*, 2003). So, cultivar improvement by using this intraspecific variability presents an important alternative to the currently unfeasible interspecific hybridization. This approach is currently used to genetically improve faba bean against several important sources of biotic stress, such as fungal diseases caused by rust (*U. viciae-fabae*), mildew (*Peronospora viciae*), chocolate spot (*B. fabae*), *Ascochyta* blight (*A. fabae*), or the parasitic species broomrape (*O. crenata*). In addition to these rather classical breeding approaches, the application of DNA markers and other molecular tools led to

precise mapping and isolation of several faba bean genes. For example, three amino acids permeases, VfAAP1, VfAAP3, and VfAAP4, from faba bean, have been cloned from a seed-specific cDNA library (Miranda *et al.*, 2001). The same group reported the cloning of two putative peptide transporter homologues VfPTR1 and VfPTR2. In the future these candidate genes could be used to manipulate the amounts and composition of storage proteins in faba bean seeds.

The assignment of various linkage groups and even single genes to particular chromosomes was facilitated by the work on faba bean primary trisomics (Torres *et al.*, 1995; Vaz Patto *et al.*, 1999). So far five out of six possible trisomics have been generated (Pozarkova *et al.*, 2002). For the large chromosome 1, for which trisomics could not be obtained so far, a linkage map has been generated with an average 8 cM map interval (Cubero and Nadal, 2005). The integration of genetic and physical map of faba bean is further improved by techniques of flow sorting (Dolezel and Lucretti, 1995; Macas *et al.*, 1996) and *in situ* hybridization (Fuchs and Schubert, 1995). Even more, flow sorting of *V. faba* chromosomes, due to their large size, has become a model for plant chromosome sorting in general. Also, by using flow fractionation of chromosomes (Dolezel *et al.*, 2001), it should be possible to prepare chromosome-specific bacterial artificial chromosome (BAC) libraries. These BACs could be screened with marker-derived probes flanking QTL regions. Sequencing the positive BAC candidates could then lead to the identification of genetic basis of a particular QTL. In a recent flow sorting approach, microsatellite-enriched chromosome-specific DNA libraries were generated, and used for developing of novel DNA markers (Pozarkova *et al.*, 2002). Also, first attempts were undertaken to fine-map genes or QTLs responsible for resistance to fungal diseases (Avila *et al.*, 2003; Roman *et al.*, 2003) or parasitic plants (Roman *et al.*, 2002). Still, the saturation of the faba bean linkage map is rather difficult to achieve due to its huge genome size. A list of linkage maps currently available for the *V. faba* genome has been published recently (Torres *et al.*, 2006).

As a conclusion, it can be stated that the major hindrances in generating transgenic faba bean plants have been overcome. Since the wild progenitor of *V. faba* has not been determined

yet (Cubero, 1974), faba bean is considered as a genetically isolated species, unable to naturally cross with other *Vicia* species (Bond *et al.*, 1985). As a consequence, its gene pool seems rather restricted. Therefore, genetic improvement of faba bean via transgenic approaches is a possible step forward. Since, only recently, reproductive and efficient techniques for regeneration of transgenic *V. faba* plants have been established, the number of transgenes that have been introduced into the faba bean genome is so far limited to five: *bar*, *uidA*, *nptII*, *sfa8*, and *lysC* (Table 1). Nevertheless, these efforts demonstrate a proof of principle that transgenic technology can be used as one of the approaches to improve faba bean breeding. There are numerous traits that would be suitable for improving economic faba bean production. However, to complete the whole procedure of generating a commercial faba bean line, starting with the newly developed transgenic plant, then outcrossing the new trait into economically valuable genotypes, and eventually getting the approval for registration of the transgenic line, is not feasible yet, especially not in the European Union (EU) (Cubero and Nadal, 2005).

Lentil

**Huseyin A. Oktem, Ufuk Celikkol Akcay, Abdullah Tahir Bayrac,
Hamdi Kamci and Meral Yucel**

Department of Biological Sciences, Middle East Technical University, Ankara, Turkey

1. INTRODUCTION

Lentil is an annual, herbaceous pulse (grain legume) crop and is probably as old as the agriculture itself. Since its domestication in the Near East, lentil (*Lens culinaris* Medicus) remained as an important source of dietary protein in the area. Despite its importance as a source of protein through ages, the crop has received little attention to improve its yield and quality. Organized collection of germplasm and crop improvement programs have only started at early 1980s with the establishment of international agriculture centers including ICARDA (International Center for Agricultural Research in Dry Areas).

1.1 History, Origin, and Distribution

Lentil was one of the first domesticated plants as were wheat and barley. It is suggested that lentil was first cultivated in the Near East including Southern Turkey where Neolithic agriculture developed about 9000 years ago (Zohary and Hopf, 1988). By the Bronze Age, the plant had been spread throughout the Mediterranean region, Asia, and Europe, which was followed by the New World including Latin America. *L. culinaris* ssp. *orientalis*, which closely resembles the cultivated species *L. culinaris*, is widely accepted as the progenitor species. The conclusion that the cultivated lentil originated in the Near East

are from *L. culinaris* ssp. *orientalis* is based on discoveries of carbonized remains of apparent cultivated lentil in the same region over which *L. culinaris* ssp. *orientalis* is distributed (Muehlbauer *et al.*, 1995).

1.2 Botanical Description

Lentil is under the order *Rosales*, suborder *Rosineae*, family *Leguminosae*, subfamily *Papilionaceae*, and tribe *Vicieae*. After a complex taxonomic history, lentil is eventually placed in the genus *Lens* Miller. The name *Lens* describes the shape of the seed of the cultivated form of lentil. Analyzing previous findings based on origin and spread, morphological, cytological, cytogenetical observations, and more recently on the basis of isozyme and molecular studies (Ferguson and Robertson, 1996), *Lens* was reclassified by Ferguson *et al.* (2000) into seven taxa split into four species:

Lens culinaris Medikus subsp. *culinaris*
subsp. *orientalis* (Boiss.) Ponert
subsp. *tomentosus* (Ladiz.) Ferguson *et al.* (2000)
subsp. *odemensis* (Ladiz.) Ferguson *et al.* (2000)
Lens ervoides (Brign.) Grande
Lens nigricans (M. Bieb.) Godr.
Lens lamottei Czeffr.

Most lentil researchers now accept this latest classification (Sarker and Erskine, 2006). *Lens*

orientalis is the presumed progenitor of cultivated *L. culinaris* Medik. The last name is for Medikus, a German botanist-physician who has given the name to the plant in 1787.

Lentil plants are typically short, slender, semierect annuals varying between 15 cm to 75 cm height depending on the genotype and environmental conditions (Figure 1). Individual plants may bear single stems or may be multibranched. Branches may arise directly from the main stem or from the cotyledonary node below ground or they may rise from other branches depending on the available space in the field and environmental conditions (Saxena and Hawtin, 1981).

The plants have slender tap roots and a mass of fibrous lateral roots. Various types of root systems, ranging from shallow branched roots to deep tap roots, are recognized depending on the texture of soil and climate in the area (Nezamuddin, 1970). The tap root and the lateral roots in the upper layers of the soil carry numerous small, round, or elongated nodules that start to decline before the onset of flowering (Saxena and Hawtin, 1981).

Lens species are diploid plants with $2n = 14$ chromosomes. They all have similar karyotypes consisting of three pairs of metacentric or submetacentric chromosomes, three pairs of acrocentric chromosomes, and one satellited pair of chromosomes (Slinkard, 1985).

Lentil plants complete their life cycle in 3–4 months under optimum environmental conditions. These conditions are usually reached in spring-sown crop, but in winter-sown crop, growth duration delays up to 30–60 days, especially in the earlier stages of growth, because of the suboptimal temperatures. Optimum temperatures for lentil seed germination is in the range of 15–25°C, but above 0°C seeds can germinate. Optimum temperatures for growth and yield are around 24°C.

Due to the hypogeal germination, in which cotyledons remain below the ground, lentil plants are less likely to be killed by freezing, wind, insect damage, and grazing. If the young shoots are damaged, new buds can be initiated from the nodes below ground. The crop is also said to tolerate drought better than waterlogged soils (Hawtin *et al.*, 1980). Throughout the world, a large proportion of the lentil crop is grown in semiarid regions without the benefit of irrigation. In most of these regions, agriculture depends on

Figure 1 Morphological characteristics of lentil [Reproduced from Kamci (2004)]

water conserved in the soil after fall and winter rains. Lentils show adaptability to a wide range of soil types. They are grown in sandy loam soils, alluvial soils, black cotton soils, or in heavier clay soils (Nezamuddin, 1970). On soils with very high

natural fertility and excessive soil moisture, the crop might make excessive vegetative growth but this reduces seed yield (Saxena, 1980).

Lentils grow well on slightly acidic soils (pH 5.5–6.5) to moderately alkaline soils (pH 7.5–9.0). Delayed nodulation and decreased yields have been obtained when the pH of the soil increased beyond 9 (Bharadawaj, 1975).

Most genotypes of lentil are very sensitive to soil salinity. Especially in the irrigated lentil growing areas, this becomes a major constraint in obtaining good yields. Salt tolerance of lentils was reported to be much less than that of most cereals, chickpeas, lupins, and faba beans although it is higher than that of *Phaseolus* bean, cowpeas, and soybeans (Ivanov, 1973).

1.3 Economic Importance

Lentil is one of the principal food crops cultivated in the semiarid regions of the world, particularly in the Indian subcontinent and in the dry areas of the Middle East (Muehlbauer *et al.*, 1995). Of the countries that produce lentil, India, Turkey, Canada, the United States, Australia, and Syria can be considered as the major producers. All the major lentil-producing countries are also major consumers, except the United States, Canada, and Australia. Other countries of the Middle East such as Egypt, Jordan, Algeria, Iraq, and Lebanon are major consumers of lentil but not major producers. Other major lentil importing countries include Spain, Colombia, Sri Lanka, and India.

Lentil has been produced on a commercial basis in the Palouse region of the United States since 1937 (Youngman, 1968). The area is characterized by loess-rolling hills with elevations of up to 900 m. In that region, lentil is most often grown in rotation with cereals where it offers a needed alternative to break cereal disease cycles, provides a crop where grassy weeds can be adequately controlled, and through nitrogen fixation, reduces the demand for nitrogen fertilizers (Muehlbauer *et al.*, 1995). In Canada, lentils are grown primarily in Saskatchewan. This province is now the second largest producer after India, with an area of about 700 000 ha (Sarker and Erskine, 2006). In Turkey, a steady increase in the sown area and production of lentil has occurred since the late 1970s. However,

a major change in Turkey's lentil production took place after 1982 with the implementation of the utilization of fallow areas project but area sown to lentil and the production has been decreasing since 1989 (Bayaner and Holloway, 1998). World lentil production has tripled in the last three decades from 1.05 million metric tons in 1971 to 3.8 million metric tons in 2004, through a 124% increase in sown area and a 58% increase in average national yield from 611–966 kg ha⁻¹ (FAO, 2004).

Lentil is a nutritious food legume. The seeds are rich in protein with concentrations averaging 26%. This value is comparable with that of faba bean, higher than that of chickpea and more than double that of wheat. However, like other grain legumes, there is a shortage of tryptophan and the sulfur-containing amino acids, methionine and cystine, which are relatively rich in cereals (Adsule *et al.*, 1989). The protein in lentils contains significant concentrations of lysine, a limiting amino acid in cereals. Therefore, when cereals and lentils are consumed together, they provide adequate amounts of essential amino acids in the human diet. Seed composition varies with genotype, seed maturity, and soil nutrient availability (Summerfield, 1981; Muehlbauer *et al.*, 1995). Lentils, like chickpeas and faba beans, are good sources of vitamin B, but are poor in carotene and vitamin C.

Even though lentils are considered to be highly nutritious, they contain antinutritional factors such as trypsin inhibitors, hemagglutinins, and oligosaccharides that cause flatulence. The toxic factors are heat labile and are almost completely destroyed after 20 min of autoclaving, but cooking have no influence on flatulence. A major use of lentil as food is in decorticated and split form, which is a principal ingredient in soups and various dishes. Residues from threshing of the lentil crop such as dried leaves, stems, and fruit walls are also essential for livestock feeding. One cultivar of lentil (Indian head), which has the capability of producing an abundance of foliar material, is used as a green manure in Canada to improve soil nutritional status. Also to grow lentils in rotation with other crops has the advantage of fixing nitrogen when effectively nodulated, thus reducing the demand for nitrogen fertilizers and depletion of inorganic nitrogen from soil (Muehlbauer *et al.*, 1995).

1.4 Traditional Breeding

Lentil breeding programs throughout the world have similar objectives with larger and more stable seed yield being the most important (Muehlbauer *et al.*, 1995). The yield limiting factors are lack of seedling vigor, slow leaf area development, high rate of flower drop, low proportion of pod setting, poor dry matter accumulation, low harvest index, lack of lodging resistance, low or no response to inputs, and various biotic and abiotic stresses (Sarker and Erskine, 2006).

Abiotic stresses that affect lentil were listed as cold, drought, heat, salinity, nutrient deficiency, and nutrient toxicity by Singh and Saxena (1993). Of these stresses, drought and heat are considered the most important worldwide (Turner *et al.*, 2001). Cold stress was considered important in the West Asia–North Africa region. Salinity is an important stress factor in the Indian subcontinent and to some extent in West Asia–North Africa. Nutrient deficiency and nutrient toxicity is of lesser importance worldwide but important in localized regions (Muehlbauer *et al.*, 2006).

Foliar diseases are the most serious biotic stresses affecting lentil crops (Muehlbauer *et al.*, 2006). *Ascochyta* blight caused by *Ascochyta lentis* is problematic to various degrees in all lentil growing regions of the world, but especially damaging in Canada (Ahmed and Morrall, 1996; Ahmed *et al.*, 1996), Australia, and Middle Eastern countries (Johansen *et al.*, 1994). Other major biotic stresses of lentil include Anthracnose caused by *Colletotrichum truncatum*, botrytis gray mold caused by *Botrytis fabae* and *Botrytis cinerea*, *Stemphylium* blight caused by *Stemphylium botryosum*, lentil rust caused by *Uromyces fabae* and sclerotinia white mold caused by *Sclerotinia sclerotiorum* (Muehlbauer *et al.*, 2006).

The methods of breeding lentil are similar to those utilized in breeding other self-pollinated crops and include pure line selection or hybridization followed by bulk method, pedigree method, single-seed descent, or some modification of these procedures (Muehlbauer *et al.*, 2006).

Although lentils are of ancient origin, systematic research on lentil improvement has begun very recently. In a recent review, Sarker and Erskine (2006) mentioned about the large number of germplasm that have been collected, evaluated,

and preserved at national and international levels, with ICARDA holding the largest collection of cultivated and wild germplasm accessions. Identification and usage of genotypes with resistance to various biotic and abiotic stresses, particularly resistance to vascular wilt, rust, and *Ascochyta* blight, and the breeding of new genotypes with good standing ability, which are suitable for mechanical harvest in West Asia and North Africa were listed among the major achievements in lentil breeding.

Lentil breeding has also led to high-yielding varieties with greater yield of biomass and breeding for resistance to lodging, pod shattering, and a different plant growth habit has increased the yield potential considerably and facilitated mechanized harvesting (Christou, 1997).

1.5 Limitations of Conventional Breeding and Rationale for Transgenic Breeding

Improvement of lentil by conventional breeding tools is limited by the availability of novel genes in the current breeding germplasm pool. Another constraint in breeding programs is the limited crossability of the cultivated *L. culinaris* with other wild allied species and production of fully fertile progenies. These problems can easily be overcome by the use of transgene technology.

Transgenic plant breeding may also allow elimination of antinutritional factors such as trypsin inhibitors and hemagglutinins by the use of antisense techniques. The technology can also be used for the improvement of nutritional quality of lentil proteins, which are characterized by a shortage of methionine and cysteine. Since lentil is one of the few crops that can be grown in the semiarid regions of the world, this can have a significant impact for the improvement of dietary intakes of people living in areas with poor soils and limited rainfall.

2. DEVELOPMENT OF TRANSGENIC LENTILS

Among all the plants used by humans, legumes are nearly as important as cereals in terms of nutritional value and uses. However, while much effort was spent in the past years on cereals like

corn, wheat and barley, legumes, except the crops including soybean and peanuts, have received little attention. Difficulty in applying the tools of genetic engineering in legumes, their recalcitrance for regeneration to a viable plant and lack of intense attention retarded transgenic plant development in lentil. Limited report on lentil engineering has been published so far and a need for a reproducible transformation system with an efficient selection and regeneration method is not totally fulfilled.

2.1 Donor Genes

Virtually in all of the *Agrobacterium*-mediated transformation optimization studies (Warkentin and McHughen, 1992; Warkentin and McHughen, 1993; Lurquin *et al.*, 1998; Mahmoudian *et al.*, 2002a, b) and also in a study that aims the optimization of gene delivery in lentil cotyledonary nodes using particle bombardment (Oktem *et al.*, 1999), p35SGUSINT vector containing kanamycin resistance gene (*NOS-NPTII-NOS*) and intron containing β -glucuronidase (*GUS*) gene was used. The vector was obtained by cloning *GUS* gene cassette with cauliflower mosaic virus 35S promoter and terminator from pGUSINT plasmid into Stratagene pBS vector (Vancanneyt *et al.*, 1990).

Maccarrone *et al.* (1992) used a different design for liposome-mediated gene transfer. pCaMVCN with chloramphenicol-acetyltransferase (*CAT*) reporter gene, pBI121 and pBI221 both carrying *GUS* reporter gene were used as vectors in the study. Following this study Maccarrone *et al.* (1995) exploited the liposome-mediated transfection of lentil protoplasts for understanding the function of the *LOX* gene. In the study different *LOX* cDNA (complementary DNA) fragments were inserted into pAS6, which is pEMBL with the cauliflower mosaic virus (CaMV) promoter, *GUS* gene and *NOS* terminator in sense and antisense direction.

Chowrira *et al.* (1996) reported electroporation-mediated gene transfer into intact lentil tissues as well as pea, cowpea, and soybean plants. The plasmid pGPT1.0, which is constructed by cloning p35SGUSINT fragment into pUC8 vector, was used in transformation experiments. The fragment contains the *uidA* gene from *Escherichia coli* with cauliflower mosaic virus 35S promoter and *nos*

terminator. The chimeric gene is interrupted by the second intron from the potato *ST-LSI* gene.

Mahmoudian *et al.* (2002a, b) reported a vacuum infiltration-based *Agrobacterium*-mediated gene transfer method for lentil cotyledonary nodes. In the study pGUSINT binary plasmid, which is a derivative of pBI121, was used. It contains coding sequences of neomycinphosphotransferase-II (*nptII*) conferring resistance to kanamycin and an intron containing *uidA* gene.

In another study reporting particle bombardment-mediated transformation of lentil, pBUC19 plasmid with chimeric SuRA/SuRB Hra acetolactate synthase gene (*ALS*) from tobacco, conferring resistance to sulfonylurea herbicides was used in the transformation of cotyledonary nodes (Gulati *et al.*, 2002). The chimeric gene was constructed by inserting a fragment of the mutant *SuRB S4-Hra* gene containing the two mutations into the mutant *SuRA C3* gene (Lee *et al.*, 1988) producing a chimeric gene of 4637 base pairs including the endogenous tobacco *SuRA C3* promoter and terminator.

2.2 Methods Employed

First transformation study in lentil by *Agrobacterium tumefaciens* was performed by Warkentin and McHughen in 1991. In this study oncogenic strains of *A. tumefaciens* are directly used without any modification. Researchers evaluated the susceptibility of lentil to four diverse strains of *A. tumefaciens* at the whole plant level *in vivo* and at explant level *in vitro*. C58, Ach5, GV3111, and A281 strains were capable of inducing tumors at high frequency on inoculated stems of lentil *in vivo*, and on excised shoot apices *in vitro*. GV3111 and Ach5 were the most effective *in vivo* and A280 was the most effective *in vitro*. Transformation was proved by nopaline and octopine assays with negative and positive controls. Also the integration of transfer DNA (T-DNA) into the genome was confirmed by Southern analysis with the probe designed for *NOS* gene plus some 5' flanking sequences. Later in 2002, a similar study on crown gall induction was carried out by Khawar and Özcan successfully to evaluate the virulence of A281 strain on different genotypes of lentil.

Following their study in 1991, Warkentin and McHughen (1992) continued with their

lentil transformation studies by using GV2260 *Agrobacterium* strain and p35GUSINT vector. It was an optimization experiment in which lentil seedlings from the cultivar Laird was used as a source of explants including shoot apex, epicotyl, cotyledonary node and root sections. Variables tested were co-cultivation duration, preculture duration, presence of acetosyringone in co-culture media, and type of wounding. Increase in co-cultivation duration was accompanied by an insignificant increase in the number of transformed explants. On the other hand preculturing had a negative effect. Different wounding strategies along with acetosyringone in co-cultivation media did not enhance transformation efficiency. In general, explant sections proximal to actively dividing centers like root tips, cotyledonary nodes, and apical meristems produced higher GUS scores when compared to other explant zones. However, overall transformation rate was low with a small number of cells transformed.

Warkentin and McHughen (1993) also investigated the susceptibility of the cotyledonary node explants of lentil seedlings (cv. Laird) to GV2260/p35SGUSINT. In the study, cotyledonary node explant was used for its capacity of high frequency shoot regeneration from axil region under 6-benzylaminopurine (BAP) induction. During shoot regeneration on selective media, no GUS positive shoot was recovered. The possible cause was assigned to immense wounding of explants with scalpel followed by bacterial inoculation. Therefore, a procedure that relies on a more gentle wounding technique like microprojectile bombardment was suggested for the transformation of cotyledonary nodes.

Lurquin *et al.* (1998) used longitudinally sliced embryonic axes from pea and lentil mature seeds, co-cultivated with *A. tumefaciens* carrying *GUS* gene to evaluate the efficiency of gene transfer to tissues in different cultivars and co-cultivation conditions, which are two different pH values for bacterial growth media and absence/presence of acetosyringone. The group claims that the technique can be used to evaluate performance of pea and lentil genotypes in co-cultivation with *Agrobacterium*.

In the study by Mahmoudian *et al.* (2002a, b) cotyledonary nodes were infiltrated with *Agrobacterium* strain GV2260. Differing from the preceding works, *Agrobacterium* cells were

concentrated prior to inoculation with explant. A mild infiltration process increased transient GUS activity significantly. The most effective factor for higher rate of transformation frequency was assigned to the use of higher concentration of *Agrobacterium* cells during inoculation.

Chowrira *et al.* (1996) reported the only electroporation-mediated transformation study in lentil. The group obtained transgenic R₂ plants using *in planta* electroporation-mediated gene transfer on lentil nodal axillary buds *in vivo*. The branches that grew out of nodal meristems were reported to be chimeric. Seeds originating on these chimeric branches were shown to be positive by Southern blot hybridization. It was also reported that the same system was applied to pea, cowpea, and soybean plants and transgenic R₁ plants were recovered from seeds originating on the chimeric branches that grew out of the electroporated nodal meristems. The group reported unusual non-Mendelian R₂ segregation ratios that showed bias against transgene presence or expression but did not provide further supporting data.

Oktem *et al.* (1999) reported *GUS* gene delivery and expression in lentil cotyledonary nodes using particle bombardment. In the study an electronic processor controlled GeneboosterTM (Jenes *et al.*, 1997) particle delivery system was used. *GUS* expressing sectors were seen on 4% of the regenerating shoots.

Gulati *et al.* (2002) used particle bombardment-based gene transfer in lentil. PDS 1000/He delivery system (Biorad Laboratories, Hercules, CA) was used with a vacuum pressure of 66 cm of mercury. Different rupture pressures (650–1800 psi) and explant preculture periods (0–6 days) were evaluated. The study provided a reproducible genetic transformation system for lentil.

In another study, five different *Agrobacterium* strains: LBA4404, EHA105, GV2260, C58C1, and KYRT1, and two different binary plasmids: pGUSINT and pTJK136 containing *GUS* and *nptII* genes were tested for the best transformation response in lentil (Celikkol, 2002). In the study, also the factors affecting *A. tumefaciens*-mediated transformation efficiency like wounding method (microcarrier and needle mediated), presence of vacuum infiltration and cultivar effect for Firat-87 and Sultan-1 cultivars were analyzed. The succinamopine type KYRT1 strain harboring the

pTJK136 plasmid exhibited the highest transient *GUS* expression for both cultivars. Microwounding (at different gas pressure and micro-carrier concentrations), either alone or in combination with vacuum infiltration did not significantly enhance gene delivery as scored by transient *GUS* gene expression. By the use of best strain/plasmid couple and needle wounding, transgenic shoots were regenerated from cotyledonary nodes with 0.8% efficiency, micrografted to root stocks, and successfully transferred to soil (Figure 2).

The first successful transfection of lentil protoplasts with liposomes was carried out

by Maccarrone *et al.* (1992). They used cationic liposomes made up of different dipalmitoylphosphatidylcholine (DPPC) and sterylamine (SA). The best results were obtained with a ratio of DPPC to SA of 9, which formed a homogenous population of round vesicles. These liposomes were able to transfect lentil protoplasts with two different reporter genes: *CAT* and *GUS*. The activity of these two enzymes could be found in the cell lysates after 24 h from the incubation of protoplasts with the lipid-DNA complexes.

The same group, in their antisense-based transformation study, used electroporation for

Figure 2 Gus expression and regeneration of transgenic lentil shoots originated from cotyledonary nodes [Reproduced from Celikkol (2002)]

transformation of lentil protoplasts (Maccarrone *et al.*, 1995). For this purpose, protoplasts were transferred into 0.4 cm electroporation cuvettes containing 15 μg of carrier DNA (sheared salmon sperm DNA) and 25 μg of plasmid in a final volume of 800 μL . Samples were electroporated with exponentially decaying pulses at field strength of 400 V cm^{-1} and capacitance of 960 μF . The group successfully transformed the protoplasts of lentil and succeeded in inhibition of *LOX* gene by using full-length sequence of the cDNA. It is obvious that the gene transfer to lentil protoplasts can be a valuable alternative to other transformation systems. It has greater efficiency and easy to handle. The only obstacle on this method is the generation of fertile plants from these protoplasts.

2.3 Selection of Transformed Tissue

Since all of the transformation attempts so far depended on direct regeneration of the plantlets from mature meristematic tissues, selection of transformants was always a problem in lentil genetic modification studies.

In the first transformation study on lentil, by Warkentin and McHughen (1992), selection of transformed tissues was done by the use of kanamycin, which was found to be very inefficient for the type of explant used. When the formation of small transformed sectors on the cotyledonary node explants, which is the result of very low transformation efficiency, combined with the death of adjacent nontransformed tissues under selection pressure, growth of transformed cells were completely inhibited. On the other hand, lower doses of kanamycin caused increase in the number of escape shoots.

Chowrira *et al.* (1996) claimed that upon electroporation on the nodes of 100 plants, 18 GUS positive chimeric R_0 shoots were generated, which were assessed by histochemical GUS staining. The R_1 progeny of 10 of these plants were further analyzed and 22 of 88 individuals were found to be GUS positive. Also it was reported that three R_2 lines were analyzed and 4 out of 34 plants showed GUS expression. These ratios indicate problems about either presence or expression of *uidA* gene in the plants on the basis of Mendelian inheritance patterns.

In the study of Gulati *et al.* (2002), selection of transformed tissues was done by the use of 5 nM herbicide chlorsulfuron. After 4 weeks of selection, proliferated shoots were allowed to elongate by reducing the concentration of chlorsulfuron to 2.5 nM. Green and healthy shoots were excised and micrografted. Out of 600 explants bombarded with 900 psi rupture pressure in sets of 25–30 explants per shot, 36 putative transformants were successfully transferred to soil, resulting in 6% transformation efficiency. In another set of experiments with 190 explants bombarded with 1100 psi rupture pressure, six putative transformants were transferred to soil, providing 3.1% transformation efficiency. Putative T_0 transformants were also tested for herbicide tolerance by using metsulfuron herbicide leaflet painting assay.

2.4 Regeneration of Whole Plant

Legumes are, in general, considered as recalcitrant plants for tissue culture and genetic modification studies, among which lentils are the most difficult to regenerate into whole plants. Since transformation studies ended up with whole plant regeneration and seed formation are scarce, tissue culture studies gain a special importance on the way of developing transgenic lentil. For this reason, in addition to the studies on transgenic plant regeneration, sole plant regeneration attempts are also included in this section.

In vitro propagation techniques are important tools for modern plant improvement programs. Since lentil is recalcitrant to tissue culture, only few considerable plant regeneration systems have been achieved up to date. First report about lentil tissue culture is regeneration from cultured shoot tips (Bajaj, 1979). This study was followed by determination of regeneration capacity of shoot meristems and epicotyls from calli induced by gibberellic acid and kinetin (Williams and McHughen, 1986). The most responsive explant hormone combination was found to be shoot meristem with 10 mg l^{-1} Kin and 1 mg l^{-1} of GA_3 . For this combination 60% of callus bodies gave rise to shoots with mean shoot number of 2.4. Also low regeneration capacity of epicotyls was demonstrated on the same hormone combination.

Calli-derived shoots of cultivar Eston were rooted with 11% efficiency in mist chamber.

Although somatic embryogenesis has been demonstrated in numerous species, plant regeneration of lentil through somatic embryogenesis has only been reported by Saxena and King (1987). In that study, plants were regenerated by the process of somatic embryogenesis from embryo-derived callus cultures of *L. culinaris* Medik. cv. Laird. The callus originated from embryonal axes cultured on modified B₅ medium containing ammonium nitrate supplemented with 1–10 mg l⁻¹ 2,4-D. Formed callus was then transferred to medium containing BAP and indole 3-acetic acid (IAA), then this callus differentiated into several embryoid like structures. Upon further subculture of the embryoid like structures on glutathione-supplemented medium, well-organized embryos were formed and developed into whole plants. Up to this date, no progress has been made toward developing an *in vitro* regeneration system based on somatic embryogenesis.

Polanco *et al.* (1988) reported the influence of different growth regulators and explant types on callus and shoot formation. In their study, three different cultivars (Verdina, Pardina, and Castellana) were used and shoot tip, first node, and first pair of leaves were utilized as explant source. It was reported that 2,4-D induced callus formation in all explants, but no organ regeneration obtained from this calli. Multiple shoot formation from 33% to 92% was obtained from explants supplemented with BAP and NAA (α -naphthaleneacetic acid). Root formation was achieved only in media with NAA or IAA.

Singh and Raghuvanshi (1989) reported direct and indirect organogenesis from lentil shoot tips and nodal segments. Kinetin in combination with 2,4-D was used for callus induction. Callus-derived shoot regeneration or direct shoot regeneration was carried out with high kinetin concentration in tissue culture. For both direct and indirect shoot regeneration studies, shoot tip was found to be the most responsive explant type.

First protoplast study in lentil was carried out by Rozwadowski *et al.* (1990). Isolation was achieved by the use of 1% cellulase, 0.5% driselase, and 0.25% pectolyase. After purification, protoplasts were cultured in medium lacking amino acids and ammonium nitrate but containing 0.35 M glucose and a growth regulator complement of

either 2,4-D, NAA, kinetin, BAP, zeatin, GA₃, or NAA and each of 2,4-D and BAP. The osmotic potential of the liquid medium was gradually reduced by lowering the glucose concentration. About 6% of the dividing protoplasts developed into cell colonies after 3 weeks of culture. In 35–42 days, the microcolonies were about 1 mm in diameter and developed into calli on transfer to agar-solidified B₅ medium supplemented with glutamine. Attempts to regenerate plants from protoplast-derived calli were unsuccessful.

The objective of the study carried out by Malik and Saxena (1992) was to explore the potential of thidiazuran (TDZ) as an inductive signal for shoot initiation potential for seedlings of different legume species (*Pisum sativum*, *Cicer arietinum*, *L. culinaris*, Medik cultivar Eston). Upon optimal TDZ (10 μ M) treatment, secondary shoot buds developed from the axils and bases of multiple shoots of mature lentil seedlings. About 19 shoots per seed were recovered from lentil. Although developing shoots of *P. sativum* were able to form roots, TDZ at 5 μ M or a higher concentration suppressed the development of primary roots and completely blocked secondary root formation in both lentil and chickpea.

In the genetic transformation study of the Warkentin and McHughen (1993) rooting of the regenerated shoots (GUS negative) was carried out in half-strength B₅ with or without NAA and scored within 1–2 months duration. 53% and 34% rooting were scored for B₅ and B₅+NAA containing media, respectively.

In another study that aimed at interspecific hybridization of different *Lens* species, media was optimized for shoot regeneration from nodal segments *in vitro* without callus phase to avoid polygeny (Ahmad *et al.*, 1997). Concentration of growth regulators, MS salts, and presence of sucrose for direct regeneration *in vitro* were analyzed. A protocol was standardized for regeneration of two shoots in average from nodes in MS media with 2.89 μ M GA, 1.11 μ M BAP, and without sucrose. The study claimed that 90% efficiency of root induction was observed upon 5.37 μ M NAA treatment. Since the study reports very low efficiency of shoot regeneration, it can be regarded as unsuitable for *in vitro* micropropagation studies that aims transgenic plant development.

The effect of BAP on root formation from lentil shoots regenerated on BAP containing media was

studied by Polanco and Ruiz (1997). Regeneration of multiple bud shoots and formation of roots were examined on seedling shoot tips, first nodes, bractlets, and immature seeds of the cultivar Verdina. Media with 2.25 mg l^{-1} BAP induced buds and shoots but no roots. Root formation was only induced on media with a low concentration of BAP (0.225 mg l^{-1}) or without BAP. In these media, the highest percentages of explants forming roots were obtained from bractlets and immature seeds on rooting media containing 2 mg l^{-1} IAA. However, these roots were unable to keep the plants alive outside the culture flask. When shoots were maintained for 4 weeks on the shoot initiation media, rooting up to 40% was obtained. The inhibitory effect of BAP on rooting increased with the duration of culture on initiation media, reaching the maximum of inhibition when regenerated shoots were maintained for 8 weeks in culture. In conclusion, given that BAP is routinely added to tissue culture to stimulate shoot regeneration, the concentration of BAP and time in culture must be carefully chosen in the micropropagation process of lentil in order to avoid BAP-induced inhibition of rooting in regenerated shoots.

Efficient and simple method of plantlet regeneration was described from immature seeds of different sizes (1–6 mm) of four different lentil cultivars: Verdina, Pardina, Lupa, and Alpo (Polanco and Ruiz, 2001). Shoot regeneration from the auxiliary meristems of the immature seeds were mediated mainly by the various concentrations of BAP in combination with gibberellins and auxins (NAA, IAA, 2,4-D). In all cultures, the best shoot regeneration response was achieved with seeds that were 5–6 mm in size ranging between 80% and 100%. In this study, it was claimed that the highest rooting efficiency was obtained with the low incubation periods in cytokinin containing regeneration medium (a period of 4 weeks), but it is obviously seen that the highest rooting efficiency in the study, which is 88.9%, is the result of the absence of BAP in regeneration media.

Gulati *et al.* (2001) reported a protocol for micrografting of lentil shoots. BAP at $8.8 \mu\text{M}$ induced the maximum number of shoots (4.3 shoots/explant) within 8 weeks. The regenerated shoots were micrografted on 5–6 days old rootstocks with 96% efficiency. Shoots were micrografted on 5–6 days old rootstocks with 96% efficiency. The successful grafts were transplanted

to pots in Redi-earthTM, hardened off and were grown to maturity with 100% success. The grafted plants were phenotypically normal and produced normal pods and viable seeds. The success of micrografting was independent of the nature and concentration of growth regulator used in shoot initiation medium and the time period for induction of shoots. The protocol was successful with several cultivars of lentil.

In another study, Fratini and Ruiz (2002) reported the effect of kinetin, zeatin, TDZ, and BAP on root regeneration. TDZ and BAP were found to inhibit root development more than kinetin (KIN) and zeatin ribside (ZEA). The study concluded that TDZ and BAP were more inhibitory for root development than KIN and ZEA, which is also in agreement with the study of Polanco and Ruiz (2001).

Khawar and Özcan (2002) tested shoot regeneration capacities of cotyledonary node explants from 21 different lentil genotypes on MS medium containing $0.225 \mu\text{M}$ TDZ. The highest shoot regeneration was 20.6 shoots/explants with Akm 362 genotype. Regenerated shoots were cultured for rooting but root formation was not achieved. To overcome rooting problem, regenerated shoots were micrografted to cultivar Kayı 91 with 100% efficiency.

The major limiting factor in the establishment of a successful plant regeneration system from *in vitro* regenerated shoots for lentil is the low frequency of rooting. There are only a few reports of rooting from regenerated shoots in lentil. It is a slow process taking 4–8 weeks and it is negatively affected from the presence of BAP (which is a very effective and widely used cytokinin for shoot regeneration in lentil) on *in vitro* regeneration medium (Polanco and Ruiz, 1997). Even if rooting is successful *in vitro*, high mortality rates are observed upon transplantation to soil, due to agar medium adapted roots with incompletely developed vascular tissues.

To fulfill the requirement of an improved and reproducible rooting procedure, Fratini and Ruiz (2003) established a rooting method for lentil, which is claimed to be based on explant polarity. Nodal segments of lentil with an axillary bud cultured in an inverted orientation (apical end in medium) showed higher rooting frequencies than explants cultured in a normal orientation (basal end in medium). The highest rooting

percentage (95.35%) and average number of shoots regenerated per explant (2.4) were obtained from explants placed in an inverted orientation on MS with 3% sucrose, supplemented with 5 μM IAA and 1 μM kinetin. The only limitation found was that rooting response was greatly reduced when the nodal segments were obtained from plants after the initiation of flowering.

In another study (Bayrac, 2004), optimization of regeneration system for cotyledonary petioles of lentil was carried out (Figure 3). Since lentil cotyledonary petiole is one of the most responsive tissues for *Agrobacterium*-mediated transformation, an optimized tissue culture system for this tissue will expedite the development of transgenic lentil plants. In the study, eight different medium types were employed to examine the callus induction potency of cotyledonary petiole. Except two, all tested medium yielded more than 80% callus induction. Subsequent to this study

each calli produced in different medium were transferred to nine different medium types to test the potencies of shoot induction. Only the callus induced in medium with 1 mg l^{-1} Zeatin riboside and 1 mg l^{-1} NAA yielded shoots at 8–40% frequency. The most responsive media for shooting were MS basal medium with no growth regulator, medium supplied with 1 mg l^{-1} Zeatin and 1 mg l^{-1} NAA, and medium supplied with 1 mg l^{-1} TDZ, respectively.

Another regeneration study through micrografting (Kamci, 2004), factors such as grafting type, grafting stem height, and the scion health were analyzed. In the study two graft types, namely cleft and whip type, were successfully adapted to lentil. Among the two, the whip type of grafting had better results (Figure 4). Both healthy scions and grafting to a shorter stem height provided enhancements in graft success. Also sealing round the uniting sections of the grafts increased the rate

Figure 3 Regeneration of plantlets from cotyledonary petiole tissue of lentil [Reproduced from Bayrac (2004)]

Figure 4 Grafting of lentil shoots [Reproduced from Kamci (2004)]

of graft success. Besides these factors, efficiency of chickpea as root stock was evaluated and found to be inefficient.

In a recent study, Newell *et al.* (2006) examined *in vitro* rooting of lentil nodal segments to test the conclusion of Fratini and Ruiz (2003), which states that shoot orientation has an effect on rooting. In the study, it was reported that when the proximal end was in agar (a hypotonic environment) the rooting percentage was low (9–25%) even when the orientation of the microcutting was altered by inverting the culture tube. In contrast, when the proximal end of the microcutting was in an aerobic environment (from the shoot being placed upside down in agar medium or placed normally or upside down in an aerated medium), rooting percentages were higher (62–100%). With these results Newell *et al.* (2006) concluded that the medium aeration at the proximal end of the microcutting is more important than shoot orientation for *in vitro* rooting of lentil microcuttings. Also when the very low rooting frequencies of nodal segments isolated from seedlings older than several days taken into consideration, grafting of regenerated shoots into root stocks seems to be the most reliable rooting procedure developed so far.

3. FUTURE ROAD MAP

Although lentil's contribution to human nourishment is of vital importance especially in some areas like South Asia, Africa, and Middle East, it is still considered as an underexploited crop on which little research has been done. The first priority on lentil improvement is the establishment of a reliable and reproducible transformation technique, which is followed by an efficient plant regeneration system.

Although lentil is a nutritious food legume with rich protein content averaging 26%, like other grain legumes, there is a shortage of amino acids methionine and cysteine. Engineering lentil for the production of methionine and cysteine can make the plant complete in terms of essential amino acids for human diet.

The plant is characterized by poor yield; it is highly susceptible to insect pests as well as fungi and considered to be very sensitive to wide range of herbicides. Weeds are important limiting factors for the yield of food legumes, which slow initial growth rates. If not adequately controlled, weed infestations can reduce yields by as much as 75%. In the case of parasitic weed *Orobanche crenata*,

complete crop loss can be the result (Knott and Halila, 1992).

Although lentil is moderately resistant to drought, it is known to be severely effected by salt. Especially in well-irrigated areas, soil salinity becomes a major constraint in obtaining good yields.

Lentil requires improvement for both its agronomical properties described above and its nutritional characteristics, and this field is totally open for new research.

1. INTRODUCTION

Within the genus *Phaseolus*, *Phaseolus vulgaris* or the common bean is the most important grain legume for direct food use (Broughton *et al.*, 2003). It produces seeds that are consumed worldwide as dietary protein source by millions of people, mainly in South America, India, and China. Four other *Phaseolus* species are also cultivated, although at a lower scale, namely *P. lunatus* (lima bean), *P. coccinus* (scarlet runner bean), *P. polyanthus* (year-long bean), and *P. acutifolius*, the tepary bean; and the tepary bean is the focus of this chapter.

The tepary bean is seen by many as one of the most drought tolerant annual legume in the world. The tepary bean is considered as a minor subsistence crop and, hence, is not very important from an economic point of view, as it is not widely cultivated and consumed. Nevertheless, it has some interesting characteristics. On the one hand, its tolerance to drought, high temperatures, and common bacterial blight has inspired breeders to explore the possibilities of crosses with the common bean, *P. vulgaris*, for its improvement (Muñoz *et al.*, 2004). On the other hand, the tepary bean is the only *Phaseolus* species that can easily be transformed with an *Agrobacterium*-based system, and for which several classes of transgenic plants have been described, and hence its coverage in this volume. The developed transgenics, however, are mainly designed for addressing research questions

and to our knowledge, there are no transgenic *P. acutifolius* plants beyond the research phase, neither in field trial nor in commercialization.

1.1 History, Origin, and Distribution

Archaeological findings have shown that the tepary bean was grown already in ancient times by the Indians in the southeastern United States, where it was probably introduced from Mexico 1200 years ago (Debouck, 1994). It has been recently suggested that one of two Mexican states, Sinaloa or Jalisco, could have been the center of domestication (Muñoz *et al.*, 2006).

The tepary bean is highly heat and drought resistant, and has been grown since long in Mesoamerica, mainly as a vegetable crop. It grows well in desert zones or areas with a long dry period. The cultivated form of the tepary bean is found up to an altitude of 2000 m. They can produce a good harvest with a single rain in otherwise dry conditions. When irrigated, however, it produces higher yields only up to a certain point, after which excess moisture becomes a detriment and leads to overproduction of foliage and low bean production. It appears that moisture stress is even a necessity to trigger fruiting. Thus, part of the tepary bean's secret to success in dry areas is to grow quickly when water is available. It can grow in sandy, muddy, sometimes organic soils with an optimum pH of 6.7–7.1.

P. acutifolius grows in the wild in the Sonoran Desert, with local populations on Isla Tiburon in the Sea of Cortez and in the Santa Maria mountains of Arizona (Nabhan, 1985). The present distribution of the cultivated form of *P. acutifolius* is limited and extends from Arizona and New Mexico, over Nicaragua to Costa Rica.

1.2 Botanical Description

1.2.1 Taxonomy

Kingdom: Plantae
Division: Magnoliophyta (Flowering plant)
Class: Magnoliopsida (Dicotyledons)
Order: Fabales
Family: Fabaceae (Pea family or Leguminosae)
Tribe: Phaseoleae
Genus: Phaseolus
Species: *Phaseolus acutifolius*
Variety: *Phaseolus acutifolius* Gray var. *acutifolius*

Common names: tepary bean (English), frijol tepari (Spanish), escomite (Nahuatl), bawi or bavi (O'odham/Pima), xmauym or xmayum (Mayan), tsatasi mori (Hopi) frijol piñuelero (Costa Rica) (Debouck, 1994; Nabhan and Rood, 2004).

1.2.2 Morphology

Wild tepary beans are climbers, growing up to 3 meter long, enabling it to climb desert shrubs. The cultivated varieties are more bushy types, or sometimes semiviny, growing to an average height of about 30 in. Leaves are pointed and trifoliate. The crop has a short cycle, flowering 30–40 days after germination. Autogamy appears to be dominant. The pods take about 2 months to ripen; they are short, about 3 in. long. Pods are initially green, later they dry to a light straw color and the plants completely wither. Usually there are five or six seeds per pod. The average weight of 100 cultivated tepary bean seeds are between 10 and 20 g (Zambre *et al.*, 2005) and between 2 and 5 g for the wild form (Debouck, 1994). Tepary beans (TB1 genotype) are shown in Figure 1.

P. acutifolius can be distinguished from other species of beans by its epigeal germination, sessile primary leaves, acute rhomboid folioles, pseudoracemes, two to four fruit-bearing stems, small pink or white flowers, with very small triangular bracteoles and pods that have sutures marked with five to ten ovules (Debouck, 1994).

P. acutifolius is a true diploid with a $2n$ chromosome number of 22. The 1C (or haploid) content of *P. acutifolius*, which reflects the genome size, is 0.75 pg (picogram) (Bennett and Leitch, 2005). In comparison, *P. vulgaris* has an 1C value

Figure 1 Close-up of seeds of tepary bean TB1

of 0.59 pg and its genome size has been estimated at 500–650 Mb (Broughton *et al.*, 2003).

1.3 Economic Importance

The total annual production of *Phaseolus* is around 24 million metric tons (Popelka *et al.*, 2004), but no data are found on the production of *P. acutifolius* individually. Nowadays, *P. acutifolius* is mainly grown as a minor subsistence crop in the southwest United States and adjacent Mexico. The cultivated genetic variability does not seem to have been very extensive, as judged from the few domesticated populations. This could be because the initial genetic base was already reduced at the time of its domestication.

It is likely that rural communities have conserved *P. acutifolius* because of its low agricultural requirements and short life cycle. It is mainly sown at the border of maize fields, although in southeastern United States it is also sown in small fields. Yields are estimated to be 200–900 kg ha⁻¹, with wide variations depending on sowing density and rainfall. About 1000–2000 kg ha⁻¹ is obtained with fertilizer, with harvests of up to 4 t ha⁻¹ under optimized conditions. It is noteworthy that the tepary bean can produce good yields without supplemental irrigation in the arid areas where it is cultivated, whereas most conventional beans would not even survive.

The main product of the tepary bean is dry seed, which is eaten because of its high protein (up to 30%) and carbohydrate content. In fact, the tepary bean has a slight superior nutritional value as compared to some other common beans. Besides the high protein content, it has higher levels of oil, calcium, iron, magnesium, zinc, phosphorus, and potassium. In addition, tepary beans are lower in polyunsaturated fat and in the antienzymatic compounds, which make common beans hard to digest (Hamama and Bhardwaj, 2002). Tepary dry beans are cooked like other dry beans after soaking. Sometimes dry seeds are toasted and then ground to the flour, which is mixed with water before eating. Tepary bean can also be consumed as a young tender string bean and used as fodder after harvesting.

There could be a renewed economic interest in the tepary beans for several reasons. They are promoted by specific gourmet retailers and restaur-

rants because of their nutty-tasting superior flavor, as well as a much creamier texture. In addition, organizations of native farmers who maintain traditional agriculture also promote the consumption of the tepary bean (examples are the Tohono O'odham Community, www.tocaonline.org and www.nativeseeds.org). Last but not the least, one of the main reasons for promoting cultivation of the tepary bean is to limit the use of water in subdesert areas. Its potential for introduction into desert areas (such as the American tropics, the Sahel, the Near East, India) is considerable but it has not been exploited. Tepary bean cultivation is being explored in dry areas of Africa due to its low rainfall requirements (Shisanya, 2002), Puerto Rico and Honduras (Miklas *et al.*, 1994) and is being revived in the southern states of the United States, like Arizona, where it was quite common as recently as 70 years ago. Researchers in Virginia have demonstrated that tepary beans can also produce well in the southeastern of the United States if planted in late spring, when moisture is lower than in early spring and temperatures are higher (Hamama and Bhardwaj, 2002).

1.4 Traditional Breeding

Due to the high variability within the *Phaseolus* family, genetic improvement by classical breeding of *P. vulgaris* has been quite successful (Singh, 1999). The tepary bean is usually seen as a secondary gene pool for improving the common bean, but to our knowledge, no specific programs have been carried out for improving the tepary bean itself. Debouck (1994) has suggested that *P. acutifolius* breeding could be done to improve the small seed size and the variability in colors, to decrease the susceptibility to rust, mildew, root rot, leaf miners, bruchids, and leafhoppers and to enhance tolerance to acidity of the soil and aluminum toxicity.

Thus, for *P. acutifolius*, the breeding research is still wide open and should consist of an increase in the germplasm collection, data on the biodiversity of the species, an understanding of the inheritance patterns of some of the traits of interest, and finally the setting up of tepary bean improvement programs and the distribution of tepary beans to farmers, giving them information

on the production potential of the tepary bean in dry zones.

To support cultivation and consumption of the tepary bean, research should be done to develop novel food technologies suited to leguminous vegetables (for example, industrial processing of bean proteins), which would free the farmer from market constraints. Also distributing information on the methods of consumption of tepary bean could be an option, in order to promote the use of this native legume.

1.5 Limitations of Conventional Breeding and Rationale for Transgenic Breeding

As is the case for most crops, the main targets for *Phaseolus* improvement are to breed varieties with higher yield, resistance, or at least tolerance to biotic and abiotic stresses such as diseases, pests, salinity, and drought. Other more specific legume-related breeding objectives include better taste, higher nutritional value of the seeds, reduced content of antinutritional factors, and flatulence factors, improved cooking qualities, and the prevention of early pod shattering as well as a pod distribution that would allow for easy, preferentially mechanical harvesting.

Biotechnology and the production of transgenic plants come in when a desired trait cannot be found within the germplasm of the species itself. But even if the desired trait is present in a more distant wild relative of the common bean, it is not always straightforward to introduce it through classical breeding into a bean elite cultivar, at which point transgenic approaches could also be considered. It should be emphasized in this context that classical breeding in *Phaseolus* has been quite successful, although interspecific crosses, like between *P. vulgaris* and *P. acutifolius* have been proved difficult (Mejía-Jiménez *et al.*, 1994; Muñoz *et al.*, 2004).

Most legumes suffer from insects that attack both the leaves and the pods, and during growth as well as postharvest, and few legume genes have been found that could confer resistance but often providing a limited tolerance to the pest. *Phaseolus* also suffers from pre and postharvest insects such as bean pod borers, bruchids, and weevils, which can be very devastating for economic value

(Singh, 1999). The expression of non-native arcelin genes, isolated from wild *P. vulgaris* varieties, and linked to resistance against Mexican bean weevil, *Zabrotes subfasciatus* (Boheman), has been evaluated with regard to insect resistance. For this, *P. acutifolius* lines have been obtained with high levels of arcelin expression, but these only show a marginal lower resistance toward the bean bruchid, *Z. subfasciatus* (see below; Goossens *et al.*, 2000; Zambre *et al.*, 2005). Another approach will be to use genes encoding insecticidal proteins. Such genes have been extensively used in transgenic plants, such as maize and cotton, but only to a limited extent in legumes (Shade *et al.*, 1994). The genes used are mainly isolated from bacteria *Bacillus thuringiensis*, and also from higher plants. The latter includes genes for lectins, proteases, protease inhibitors, and α -amylase inhibitors.

A particular application that has been extensively studied in legumes, in general, is the improvement of the nutritional quality of the seeds, especially to increase the methionine content (Wang *et al.*, 2003). A low seed-methionine content is a common problem for all legumes and classical breeding has not been very effective in this field. The heterologous expression of methionine-rich proteins has been shown to be possible (Molvig *et al.*, 1997; Dinkins *et al.*, 2001; De Clercq *et al.*, submitted). However, care should be taken so that these proteins will not cause allergic reactions as has been shown for the methionine-rich 2S albumin from Brazil nut (Nordlee *et al.*, 1996). The potential of such approaches is still largely untapped but should yield seeds with enhanced protein quality for the future, mainly in animal feed applications (White *et al.*, 2000).

Another target for legume improvement through transgenics is virus resistance. Two widely spread viruses affect bean production, namely the bean golden mosaic virus and the bean yellow mosaic virus. Virus resistance has been shown to be a trait that can be introduced through genetic transformation. The strategy is based on the expression of virus related sequences that trigger the virus induced silencing system of the plant (Tenllado *et al.*, 2004). This has been used for beans by the Brazilian research center Embrapa to obtain transgenic plants tolerant to bean golden mosaic virus (Aragão *et al.*, 1998).

2. DEVELOPMENT OF TRANSGENIC TEPARY BEAN

Transformation of *P. acutifolius* is still in its early development, and has until now mainly been focused on research applications. The only transgenic plants described in literature have been generated in the group at Ghent University, Belgium. Work is also ongoing in other groups (see “transformation group” on the website of the Phaseomics Initiative: <http://www.phaseolus.net>).

Transformation of *P. acutifolius* is stable and consistently reproducible (Dillen *et al.*, 1997; De Clercq *et al.*, 2002; Zambre *et al.*, 2005; De Clercq *et al.*, submitted). The protocol described by this group is based on the generation of callus tissue from either floral buds (Dillen *et al.*, 1996) or the cotyledonary node region (Figure 2) (Zambre *et al.*, 1998). This callus is co-cultivated with *Agrobacterium tumefaciens* for one week, followed by selection on antibiotic containing medium. β -glucuronidase (GUS) positive callus is transferred on shoot induction medium, *in vitro* developed shoots are either grafted (Figure 3) or allowed to root and then transferred to soil for further establishment in the greenhouse (Dillen *et al.*, 1997; De Clercq *et al.*, 2002; Zambre *et al.*, 2005). For details on the protocol with steps described in details consult Zambre *et al.* (2006). Using this protocol, dozens of transgenic lines have been generated, aimed at either insect resistance (Zambre *et al.*, 2005) or increased methionine content (De Clercq *et al.*, submitted). In addition, *P. acutifolius* has been evaluated as a potential crop for molecular farming (De Jaeger *et al.*, 2002).

2.1 Donor Gene

For the different transgenics that have been published, three classes of transgenes can be described.

A first category concerns the use of arcelin genes. Arcelins are seed proteins found in some wild *P. vulgaris* genotypes that are resistant to the bruchid beetle *Z. subfasciatus* (Mexican bean weevil). At least seven arcelin variants exist, each consisting of different isoforms. Resistance

Figure 2 Graft of a transgenic tepary bean shoot into a wild-type seedling

to *Z. subfasciatus* is genetically linked to the arcelin locus (Osborn *et al.*, 1988; Cardona *et al.*, 1989), and arcelin proteins have been regarded as its causal factors (Osborn *et al.*, 1988; Sales *et al.*, 2000), although direct evidence that the arcelin genes themselves are involved in resistance is lacking. To test this hypothesis, transgenic lines of *P. acutifolius* (genotypes NI576 and TB1) expressing arcelin genes (*arc1* and *arc5*) at high levels were evaluated for insect resistance.

Figure 3 Calluspiece (left) that was derived from callus forming on the cotyledonary node of a tepary bean seedling (right), as part of the transformation protocol

The results indicated that these lines were not significantly protected against *Z. subfasciatus* (Goossens *et al.*, 2000; Zambre *et al.*, 2005).

For this analysis, *A. tumefaciens* strain C58C1Rif^R containing pMP90 (Koncz and Schell 1986), a nopaline-type nononcogenic Ti plasmid, and harboring a binary plasmid vector—pATARC3 (Goossens *et al.*, 1999) or derivatives were used in all experiments. These binary vectors contained the neomycin phosphotransferase II (*nptII*) gene under control of the nopaline synthase promoter and the β -glucuronidase (GUS)-encoding gene (*uidA*) (Jefferson *et al.*, 1987) with an intron under control of the cauliflower mosaic virus (CaMV 35S) promoter. In addition, the vectors carried gene sequences from arcelin genes encoding for arcelin proteins, namely Arcelin 5a, Arcelin 5b, and Arcelin 5c as well as from Arcelin 1 (Anthony *et al.*, 1991; Goossens *et al.*, 1994). All arcelin coding sequences were under the control of the seed-specific promoter region and the 3' flanking sequence from the arcelin gene (*arc5-I*) that is encoding Arcelin 5a (Goossens *et al.*, 1999). Transgenic beans from one wild, and two different cultivated *P. acutifolius* genotypes (TB1 and PI440795), all showing high accumulation of arcelin levels were tested for their resistance to *Z. subfasciatus*, but they were only marginally less susceptible to infestation than control or

nontransgenic *P. acutifolius*. Hence, the arcelin genes tested are likely not major determinants of resistance against *Z. subfasciatus*.

A second category of transgenic plants was developed using the arcelin genes as described above but with modifications allowing them to express a modified arcelin protein with a higher number of methionines. For that purpose modified *arc5-I* genes (encoding for Arcelin 5a) were created with up to 12 additional methionine codons and were introduced into the *P. acutifolius* genotype TB1. The constructs used again were based on the same pATARC3 binary vector as described above and 5' and 3' sequences were from the *arc5-I* gene. Proteins accumulated at high levels in seeds of several independent transgenic *P. acutifolius* TB1 lines. This high accumulation level in turn resulted in some lines in a significant increase of the methionine content in the seeds of these transgenic beans (De Clercq *et al.*, submitted).

Finally, to evaluate the potential of tepary bean for molecular farming in the pharmaceutical sector, a gene encoding an antibody fragment has been expressed (De Jaeger *et al.*, 2002). These constructs were also made in the backbone of the same binary vector family, pATAG4 (Goossens *et al.*, 1999). The construct contained the neomycin phosphotransferase II (*nptII*) gene under control of the nopaline synthase promoter, with a 3' end of the octopine synthase gene. The gene of interest, in

this case the coding sequence of the murine single chain Fv binding dihydroflavonol-4-reductase of *Petunia hybrida* (De Jaeger *et al.*, 1999) was cloned under the control of the *arc5-I* promoter (4600 bp) and the first 13 bp of the 5'UTR of the *arc5-I* gene and a signal peptide of the 2S2 seed storage protein gene of *Arabidopsis thaliana* (Krebbers *et al.*, 1988). It is terminated by a KDEL (ER retention signal) and the 3' end of *arc5-I* (3900 bp).

2.2 Transformation Methods

The protocol that is described is an *Agrobacterium*-based method, whereby green nodular callus (Figure 2) is co-cultivated with a low dense *A. tumefaciens* strain C58C1 Rif^R culture (Zambre *et al.*, 2006). Among three nononcogenic Ti plasmids that were tested—the nopaline-type pMP90 (Koncz and Schell 1986), the octopine-type pGV2260 (Deblaere *et al.*, 1985), and the agropine/succinamopine-type pEHA101 (Hood *et al.*, 1986)—the first one has been shown to be most effective (De Clercq *et al.*, 2002).

Particle bombardment could be another method, although in some cases less preferred (Altpeter *et al.*, 2005) for genetic transformation. It has to our knowledge not been explored for the tepary bean transformation, although it has been successfully used to achieve genetic transformation of *P. vulgaris* (Aragão, 1998, 2002).

2.3 Selection of Transformed Tissue

After co-cultivation, transgenic calli are selected through four or five passages on media containing the antibiotic geneticin. Resistance to geneticin is conferred by the *nptII* gene that is present on the transfer DNA (T-DNA). This lengthy callus phase ensures the strict selection of transgenic callus, although the selective agent is omitted in the subsequent plant regeneration steps, essentially all obtained plants are truly transgenic.

To monitor transformation efficiency, GUS expression is checked on small parts of nice green, growing callus pieces and GUS positive calli are transferred to shoot induction medium (Zambre *et al.*, 2005, 2006).

2.4 Regeneration of Whole Plant

Shoots appearing on the shoot induction medium will in many cases form roots spontaneously. Shoots that are not rooting spontaneously are grafted (Figure 3). For this, the base of apical or nodal segments (approximately 5 mm) of 2–4 cm shoots is trimmed to obtain a wedge shape. The hypocotyls of wild type seedlings as root stocks are cut about 1.5 cm above the root by a transverse cut in the epicotyl region to remove the plumule. The scion base is inserted into a vertical hole, made with a needle in the epicotyl region of the root stock. The resulting grafts are cultured on Murashige and Skoog (MS) medium, and incubated in a growth chamber for 3 weeks. *In vitro*-established grafted shoots and spontaneously rooted shoots are transplanted to soil in 4.51 pots after washing the roots thoroughly with running tap water. Initially the plants are covered with transparent plastic to maintain humidity; thereafter, the plants are gradually acclimatized by cutting holes in the plastic to lower the humidity.

2.5 Follow-up Testings

All transgenic plants that are obtained with the above-described procedure are fertile and appear to be morphologically normal over at least four generations. Stable integration of the transgenes and transmission to the progeny in a Mendelian fashion has been demonstrated by assaying GUS expression on small pieces of the harvested dry seeds. Leaves of mature plants have been used to extract DNA and perform southern blots with different probes related to the construct that has been inserted. As ultimate proof the expression of the gene of interest is shown by western blot analysis.

2.6 Specific Regulatory Measures

As *P. acutifolius* is not a widely cultivated and consumed crop, there is not so much specific to be found in regulatory guidelines. As for the movement of legumes in general, the International guidelines for the movement of legumes has been agreed and published as “FAO/IBPGR Technical guidelines for the safe movement of

legume germplasm” (<http://www.ipgri.cgiar.org/publications/pdf/96.pdf>). A special emphasis for *P. acutifolius* is given for its seed transmission of bean common mosaic virus.

3. FUTURE ROAD MAP

3.1 Expected Products

Because of the limited scale of consumption of *P. acutifolius* not much effort has been put in attractive traits that could be introduced through genetic engineering. One area where this crop could be relevant is within the field of molecular farming. *P. acutifolius* seems to be able to express heterologous proteins at a high level, and moreover it cannot cross in the field with the more commonly consumed *P. vulgaris*, which could be perceived as an advantage by regulators in view of the prevention of transgene spread to important food crops.

It has been observed by breeders that there is a pronounced heterotic effect in tepary bean and thus a transgenic approach to create male sterile tepary beans could be an interesting and straightforward project. However, no cytoplasmic male sterility has been described for *P. acutifolius*. Transgenic approaches to introduce male sterility have been well described and consist of the expression of a cytotoxic ribonuclease, called barnase, under the control of a tapetum specific promoter (De Block *et al.*, 1997).

3.2 Addressing Risks and Concerns

As a minor subsistence crop, *P. acutifolius* is a legume that could well be more promoted, especially in drought prone areas. It is, however, not expected that the introduction of a genetically modified tepary bean, even with improved agricultural qualities, will give rise to big shifts in its use and thus in agriculture or food production. They will likely just replace other tepary bean varieties, or *P. vulgaris* or other legumes. Since tepary beans are highly adapted to adverse environmental conditions, one expects that transgenic varieties will improve economies in developing countries while maintaining traditional agricultural practices.

It must be clear that any new transgenic lines that will be developed, either with improved agricultural properties or for industrial applications, will undergo trials and safety evaluations, and when approved by the respective authorities for commercialization will be safe for human health and environment.

3.3 Expected Technologies

Major improvements are still needed for transgenic applications in *Phaseolus*, and for the complete grain legume family in general, first in relation to the transformation efficiency and secondly in relation to specific promoters that could be used.

For the first, improvement of culture-based transformation protocols is surely possible and will include testing various culture conditions, media compositions, hormones, and selection systems. However, this is a quite time-consuming approach and, to our knowledge, not many research laboratories are currently active on improving *Phaseolus* transformation protocols.

More scientific insights on tissue culture-based plant regeneration systems might also allow the development of alternative approaches to improve legume transformation. Examples are genes known to be involved in embryogenesis or cell cycle regulation, that have been shown to increase transformation frequency in maize (Gordon-Kamm *et al.*, 2002) or have this potential (Boutilier *et al.*, 2002; Zuo *et al.*, 2002; DeYoung *et al.*, 2006). Alternatively new developments in systems biology, that combine genomics, proteomics, and metabolomics, could allow for a better understanding of the *Agrobacterium* transformation process. This could lead to the identification of genes with a positive effect on transformation related steps that could be very useful in the development of *Agrobacterium* transformation systems for recalcitrant species and varieties, among which the very important *P. vulgaris*. It would be a breakthrough if *Agrobacterium* could be “engineered” in such a way that it becomes a perfect gene delivery tool for all plant systems.

For the second aspect, to obtain more specific promoters it is worthwhile to mention that an international *Phaseolus* genome initiative has been undertaken, named Phaseomics (Broughton *et al.*, 2003; <http://www.phaseolus.net>). The focus of

this program is to physically map the genome (Blair *et al.*, 2003) with the ultimate goal of sequencing it. This should deliver many more gene sequences that could be studied for their expression and function, which could eventually lead to new tissue specific or condition-induced promoters.

As already mentioned, the improvement of tepary beans by genetic engineering is at its birth. No commercial genetically modified (GM) variety is in the pipeline. The development of such varieties shall, therefore, follow the trend for safer markers and exclusion of antibiotic resistance markers. It is, however, important to stress that there is no experimental evidence of gene transfer to the bacterial gut. Nevertheless, several National Academies of Sciences have recommended the phasing out of antibiotic markers because alternative strategies are available that avoid unnecessary concerns on GM crops.

3.4 Specific Details for Intellectual Property Rights (IPR), Public Perceptions, Industrial Perspectives, Political and Economic Consequences

From an industry perspective, *P. acutifolius* might hold promises for the production of proteins of industrial or pharmacological interest, as mentioned above, as it seems to be able to express heterologous proteins at a high level in the seeds, which can also benefit from relative straightforward and well established extraction procedures. *P. acutifolius* cannot cross in the field with the more commonly consumed *P. vulgaris*, thus preventing transgene spread to this food crop. Measures should, however, be taken to avoid gene flow to wild tepary bean varieties. The above mentioned male sterility strategy could be a good option.

In addition, in view of its drought tolerant behavior, the tepary bean could become a more important crop, as water shortages become a reality in increasing regions of the world. Its use in molecular farming can be extremely beneficial for developing countries, since it will add high value to a minor local crop production. With this in mind, *P. acutifolius* should be considered as a legume crop with potential for the future and genetic improvement programs, either through classical breeding, molecular markers-assisted breeding, or

newer genetic engineering approaches, should be encouraged.

ACKNOWLEDGMENTS

The authors wish to thank Fernand Lambein, Dulce de Oliveira, and Marcelle Holsters for reading the manuscript and giving valuable comments.

1. INTRODUCTION

The genus *Vigna*, subgenus *Ceratotropis* consists of 16–17 recognized species (Tateishi, 1996), which are distributed across Asia. Asian *Vigna* species of the subgenus *Ceratotropis* constitute of an economically important group of cultivated and wild species, of which a rich diversity occurs in the Southeast Asia. *Vigna* species contribute a vital protein component to the vegetarian diet of the resource-poor populace of the underdeveloped and developing countries. The production of these species is severely limited by numerous diseases and environmental stresses. Research efforts have been initiated to increase their yield by elevating and/or imparting resistance for diseases, insect pests and rescuing from natural genetic inadequacies. In the last few decades, production of these species has been maintained mainly due to the high rate of chemicals applied (fertilizers, herbicides, pesticides, or insecticides), mechanization, as well as amelioration practices. However, these practices have resulted in severe economic and ecological implications in the developing countries. Progress in genetic improvement by conventional breeding is hampered due to the lack of sufficient and satisfactory level of genetic variability within the germplasm. Because of the lengthy process of breeding and recurrent selection, the genetic diversity of *Vigna* species has been eroded and became very narrow. Further, breeding methods became limited by low recombination potential

as an outcome of self-pollination, low inheritance capacity of some important characteristics (total yield and yield components), and embryo abortion in some interspecific hybrids. The immense potential of biotechnological tools to supplement breeding programs in developing high yielding, disease resistant, and stress tolerant *Vigna* species is being realized. Progress has been made for *in vitro* regeneration of sexually mature plants, in majority of these recalcitrant species, from various tissues. Commendable progress has been made with regard to development of robust genetic transformation systems in *Vigna* species. An overview of the *in vitro* regeneration and critical analysis of the genetic transformation studies in major *Vigna* species are presented. The bottlenecks to overcome their recalcitrance *vis-à-vis* the advantages and limitations of all those transformation techniques applicable, along with future directions in research are discussed.

1.1 Cultivation and Production

Mungbean has been widely cultivated in the Indian subcontinent and adjacent regions for several thousand years and is known to have spread to other Asian countries and northern Africa. The widespread distribution in the tropics and subtropics of Africa, West Indies, North America, and Australia is relatively recent. Presently, it is the most important grain legume in Thailand

and the Philippines; it ranks second in Sri Lanka and third in India, Burma, Bangladesh, and Indonesia. It is a minor crop in Australia, China, Iran, Kenya, Korea, Malaysia, the Middle East, Peru, Taiwan, and the United States. In India, mungbean is cultivated either as summer/spring season or rainy season crop. It is also grown in winter in South India. Recent estimates of dry bean production (includes *Phaseolus* and other *Vigna* species) in India are 7 million tons (<http://www.grainlegumes.com>).

Urdbean is an important pulse crop in India, Burma, Bangladesh, Pakistan, and Thailand, and of minor importance in Sri Lanka. It is grown in a limited scale in other parts of Southeast Asia, Australia, and Fiji. India is the leading producer of urdbean in the world contributing around 1.5 million tons, around 10% of the total quantity of pulses produced in India. Myanmar and Thailand follow India in production, though Myanmar produces mainly for export.

Azukibean is an important grain legume in East Asia especially in Japan, China, and Korea. It ranks second after soybean in Japan, the main producing district being Hokkaido. Azukibean is also grown to a greater extent in Nepal and Bhutan. In Japan, 70 000–90 000 metric tons were produced annually between 1996 and 2000. In China, azukibean is cultivated on 47 000 ha and may have an annual production of about 700 000 metric ton (Vaughan *et al.*, 2005).

1.2 Economic Importance

Asiatic beans, mungbean, and urdbean are primarily grown for its protein-rich dry edible seeds and fresh sprouts. The dried seeds are used as whole or split in making *dal*, soups, and curries and ground into flour for noodles, bread, and biscuits. The seeds have high protein (18–36%) that is easily digestible, are easy to cook and lack flatulence factors (lowest level of oligosaccharides of raffinose family—reffinose, stachyose, and verbascose shown to be responsible for flatulence) in contrast to other legumes. Seed protein is deficient in sulfur amino acids, particularly methionine and tryptophan. In contrast, the lysine content is high. Therefore, combination of mungbean/urdbean and cereal in diet provide a more balanced amino acid profile. The seeds are also rich in calcium,

phosphorous, and certain vitamins (thiamine, riboflavin, and niacin). Beside protein, mungbean also has relatively high iron content. A new variety Pusa Bold-1 (Pusa Vishal) contains 6 mg of iron per 100 g raw seeds compared to 3.3 mg or 3.5 mg in traditional varieties (Vijayalakshmi *et al.*, 2003). The iron in mungbean is made more biologically available when seeds are cooked together with certain vegetables such as tomato, mustard greens, and cabbage (Bains *et al.*, 2003). Such consumption can substantially increase the iron store of anemic school children (Weinberger, 2002). Mungbean seeds and soup are also a rich source of alkaloids, coumarin, and phytosterin that play an important role in promoting the physiological metabolism of human beings and animals. In traditional Chinese medicines, part of mungbean plants are used for treating various ailments including hepatitis, gastritis, uraemia, toxicosis, red dysentery, cholera, corneal opacity, and macula (Zheng *et al.*, 2002). The other health promoting substance, isoflavones are present at levels of 0.19 mg 100 g⁻¹ in mungbean (Yu and Mc Gonigle, 2005). Mungbean seeds are free from antinutritional factors such as trypsin inhibitor, phytohemagglutinins, and tannin (Liener, 1975; Price *et al.*, 1980).

The sprouts of both mungbeans and urdbeans are used as a green vegetable, when other vegetables are scarce. One kilogram of dry seeds of mungbean can yield 8–9 kg sprouts. With sprouting, there is an increase in thiamine, riboflavin, niacin, and ascorbic acid concentrations (Abdullah and Baldwin, 1984). Mungbean sprouts are favored throughout Asia especially in Chinese cooking, Europe, and North America where they are used as a garnish in mixed diets or used as a valuable source of protein and vitamins in vegetarian diets. The young pods are also used as a vegetable. An increased consumption of mungbean sprouts, particularly by people consuming western-type diets, could have a significant effect on cardiovascular disease, which is a major problem associated with such diet.

Besides human food, they also serves as nutritive fodder for cattle, and used as manure. All *Vigna* species are annual, nitrogen fixing, generally short-duration plants, and therefore widely used as mixed intercrop or in rotation to improve nitrogen status of the soil, and to break disease/pest cycles.

1.3 Constraints in Production

The major limitations in mungbean (*Vigna radiata*) and urdbean (*Vigna mungo*) yield are:

1. Mungbean yellow mosaic virus disease (MYMV), *Cercospora* leaf spot (*Cercospora canescens*), powdery mildew (*Erysiphe polygoni*), bacterial leaf spot (*Xanthomonas campestris* pv. *phaseoli*), anthracnose (*Colletotrichum lindemuthianum*), and *Sclerotinia* blight caused by *Sclerotinia sclerotiorum*.
2. Major insects that include whitefly (*Bemisia tabaci*), bean thrips (*Megalurothrips distalis*), gram pod borer (*Helicoverpa armigera*), and legume pod borer (*Maruca vitrata*).
3. Storage pests mainly bruchid, *Callosobruchus* species.
4. Major abiotic stresses include salinity, drought, heat and cold stress.
5. Indeterminate growth habit, defective plant type, excessive vegetative growth, low harvest index, sensitivity to photoperiod, asynchronous flowering, and shattering of pods.
6. Sprouting of seeds *in situ* following rains.

The major constraints in azukibean (*Vigna angularis*) production are postharvest damage by bruchids, azukibean weevil (*Callosobruchus chinensis*), and the cowpea weevil (*Callosobruchus maculatus*); bacterial infection; brown stem rot caused by a fungus, *Fusarium oxysporum*.

1.4 Taxonomy

Vigna cultigens and soybean are warm weather and tropical legumes of subtribe Phaseolineae of tribe Phaseoleae of subfamily Papilionoideae (Fabaceae). The genus *Vigna* savi of subtribe Phaseolineae includes seven subgenera (Marechal *et al.*, 1978) of which three subgenera, *Ceratotropis*, *Plectotropis*, and *Vigna* include cultigens. Recently, the taxonomy of the subgenus *Ceratotropis* has been revised (Doi *et al.*, 2002; Tateishi and Maxted, 2002; Tomooka *et al.*, 2002a, b). In the new system, the subgenus has been divided into three sections, *Angulares*, *Ceratotropis*, and *Aconitifolia*, consisting of 12, 4, and 5 species, respectively. Of the 21 species of subgenus *Ceratotropis*, eight are cultivated (Tomooka *et al.*, 2002b) (Table 1). Among these the widely grown are mungbean

(*V. radiata*), urdbean (*V. mungo*), and ricebean (*V. umbellata*) in the tropical countries of South and Southeast Asia and azukibean (*V. angularis*) in the East Asia.

V. radiata along with its allied species, *V. mungo*, *V. grandiflora*, and *V. subramaniana* has been placed within the subgenus *Ceratotropis* of section *Ceratotropis* as classified by molecular analyses and taxonomic studies (Doi *et al.*, 2002; Tomooka *et al.*, 2002c). These species shared several morphological traits, such as epigeal germination and elliptic to ovate first leaves without a petiole. However, cultivated and wild species of *V. radiata* are distinct from *V. mungo* with broader stipules, pale yellow flowers, more ovules per pod, spreading pods with short brown hairs, and nonarillate hilum and also in chemical and molecular characters. *V. radiata* var. *sublobata*, the wild progenitor of mungbean is distributed across tropical Africa, Oman, South and Southeast Asia, Papua New Guinea, and Australia (Tomooka *et al.*, 2004). India is considered the center of diversity of the mungbean weed (Paroda and Thomas, 1988) and wild forms (Lawn, 1995), which are found in hilly tracks of northern Terai region and Western Ghats (Arora and Nayar, 1984; Saravankumar *et al.*, 2003). India is likely the place of origin and domestication (Tomooka *et al.*, 2004) as remains of *Vigna* seeds have been reported at Indian archaeological sites dating back to 3000–3500 BC and 2500 and 3000 BC (Jain and Mehra, 1980). Indian mungbean landraces have the most diverse protein and plant growth types (Tomooka *et al.*, 1991, 1992). The mungbean landraces of Western Asia (Afghanistan–Iran–Iraq) region are considered primitive (small and variously colored seeds, plants with many laterals) with diverse protein types while those of Southeast Asia have large shiny green seeds, tall plant with thick main stem, late maturing, and simple protein types. The mungbean landraces of East Asia include growth type diversity that is intermediate between the types from Western Asia and Southeast Asian (Tomooka *et al.*, 2004).

V. angularis, which belongs to section *Angulares* of the subgenus *Ceratotropis*, is characterized by hypogeal germination, cordate first and second leaves with petioles, well-developed keel pocket in flower, and beaked style. The putative wild progenitor, *V. angularis* var. *nipponensis*, and weedy

Table 1 The cultivated and domesticated *Vigna* species

forms, which show an intermediate phenotype between cultivated and wild bean, are distributed throughout Japan that is considered to be a center of diversity for azukibean (Vaughan *et al.*, 2005).

Recent studies suggest that there are four different groups of azukibean germplasm according to their geographic origin, namely, China, Korea, Japan, and the Himalayan region. Among these, Himalayan germplasm is well differentiated from other groups (Zong *et al.*, 2003). The results suggest that azukibean was probably domesticated independently in the Himalayan region and East Asia.

1.5 Conventional Breeding

The general objectives of breeding Asiatic *Vigna* beans are to develop varieties possessing

1. high yield, early and uniform maturity (55–60 days);
2. shining green and bold seeds;
3. resistance to pathogens (that cause MYMV, *Cercospora* leaf spot, and powdery mildew) and insect pests (bruchids, thrips, and pod borer);
4. resistance to abiotic stresses (salinity, alkalinity, heat, etc.);
5. resistance to preharvest sprouting; and
6. improved nutrient content such as sulfur-containing amino acids in proteins and altered seed starch composition for use of mungbean in different foods.

Some of the sources of cultivated and wild germplasm for these traits have been identified or improved (see Jaiwal and Gulati, 1995; Srinives, 1996; Tomooka *et al.*, 2004) but durable and broad resistance to biotic and abiotic stresses are difficult to achieve through conventional breeding.

2. GENETIC TRANSFORMATION OF *VIGNA* SPECIES

Production of Asiatic *Vigna* species is severely limited by a number of biotic and abiotic stresses (Sahoo *et al.*, 2003). Genetic improvement of these bean species through conventional breeding relies on the utilization of domestic cultivars and related genera as the source of genes. Genes conferring resistance to biotic and abiotic stresses have been found in many wild or related species (Sahoo *et al.*, 2003). However, the major impediments in using the wild species as a source of resistance are cross-incompatibility with the cultivated ones, and linkage drag (Watanasit and Pichitporn, 1996). The resistance in cultivated gene pool in subgenus *Ceratotropis* is rare when compared to the wild species (Tomooka *et al.*, 2002b). Genetic barriers existing in the native *Vigna* species further prevent the transfer of useful traits to the related species (Palmer *et al.*, 2002).

Genetic engineering has opened up new avenues to modify crops providing viable solutions to alleviate the constraints in productivity (Estruch *et al.*, 1997). The process offers plant breeders access to an infinitely wide array of novel genes and traits across the organisms, which can be introduced through a single event into high-yielding and locally adapted cultivars through the conceptual framework and technical approaches of plant tissue culture and genetic transformation. Further, it is possible to control the timing, tissue specificity, and expression level of transferred genes for their optimal function. The powerful combination of genetic engineering and conventional breeding programs permits useful traits encoded by transgenes to be introduced into *Vigna* species within an economically viable time frame, saving precious time required for introgression of desired traits from the wild relatives by conventional practices. Enormous potential for genetic manipulation of these species lies in increasing resistance to diseases, pests, and abiotic stress, and qualitative change in their seed composition. Moreover, with the establishment and expansion of genomics programs, a much broader range of genes with potential for crop improvement are being identified and, in some cases, tailored and/or redesigned for further enhancement of their properties within specific crops. This has further intensified the interest

in developing efficient plant transformation technologies to be able to concurrently test and capture the value of these genes in *Vigna* species. Beyond crop improvement, the ability to engineer *Vigna* species holds a powerful and informative means for studying gene function and the regulation of physiological and developmental processes.

Development of efficient and routine genetic transformation systems in grain legumes, the *Vigna* species in particular, poses a formidable challenge in the generation of stable transgenic plants. Advances in tissue culture, combined with improvements in transformation technology, have resulted in increased transformation efficiencies in many grain legumes (Somers *et al.*, 2003). However, Asiatic *Vigna* species have still remained recalcitrant to tissue culture and are stubbornly resistant to the overtures of genetic engineering (Chandra and Pental, 2003). Further, advances in molecular genetics, e.g., gene overexpression, gene suppression, promoter analysis, and transfer DNA (T-DNA) tagging, require efficient transformation systems (Somers *et al.*, 2003).

Gene transfer to these species demands development of robust plant regeneration systems from tissues amenable to routine genetic transformation methods, efficient selection system for recovery of viable and fertile transgenic plants from transformed explants at a reasonable frequency, and a time frame in culture to avoid somaclonal variation and possible sterility (Sahoo *et al.*, 2003).

Whilst different approaches have been attempted for transformation of *Vigna* species, *Agrobacterium tumefaciens*-mediated gene transfer has been the most successful in generation of transgenic plants besides considerable progress made with regard to particle bombardment. The *Agrobacterium*-mediated genetic transformation is considered so far advantageous over direct DNA delivery techniques in its capacity for high frequency of stable genetic integration, the transfer of relatively large segments of DNA, and insertion of single/low copy numbers of gene(s) (McCormac *et al.*, 1998). The relative ease with which *Agrobacterium* may transform is likely due to the wound response these species exhibit (Potrykus, 1990); however competence of *Agrobacterium* to access the cells capable of dedifferentiation, followed by regeneration limits its success. Thus, combining transformation

competence with totipotency is imperative in this species (Birch, 1997).

Considerable progress has been made in *A. tumefaciens*-mediated genetic transformation of Asiatic *Vigna* species. A summary of the key transformation events is presented in Table 2. Severe host-genotype specificity, lack of wounding response, the choice of suitable explant source potentially competent for both regeneration and *Agrobacterium* infection have so far limited the success of the *Agrobacterium*-mediated transformation. The ultimate choice is to target as many competent cells as possible; moreover, to develop ways to maximize the number of cells (Christou, 1995).

The ability to engineer organized tissue, comprising different cell populations that are developmentally and positionally distinct, considerably limits the time duration of introduction of foreign genes into elite germplasm. Regeneration systems based on pre-existing meristems, precisely shoot apex, are promising as they develop directly into various tissues and organs of a mature plant including flowers (Ritala *et al.*, 1994; Schoneberg *et al.*, 1994; Aragao and Rech, 1997) without an intervening callus phase (Babaoglu *et al.*, 2000). The avoidance of a callus phase, followed by regeneration to shoots or somatic embryos ensures a low incidence of somaclonal variation. Particle bombardment, which relies upon the acceleration of DNA-coated particles into target cells, is much preferred option for gene delivery to recalcitrant grain legumes, circumventing the host specificity as well as genotype dependence by *Agrobacterium* (Christou, 1994, 1995, 1997). Shoot apex with its very high regeneration potential, offers an ideal target for bombardment, overcoming many of the regeneration problems (Potrykus, 1990; Kim and Minamikawa, 1996; Aragao *et al.*, 2000). Although transformation based on such tissue carries the risk of producing chimeric plants containing both transformed and untransformed sectors, regardless of whether regeneration is achieved through axillary shoot growth of organogenesis (Pigaire *et al.*, 1997), production of chimeric transformants is not always undesirable as there is evidence to indicate that wholly transformed plants can be recovered from chimeric shoots (McHughen and Jordan, 1989). The genetic transformation study in *Vigna* species is presented in Table 2.

2.1 *Vigna radiata*

Direct organogenesis pathway from cotyledon, cotyledonary nodes, and primary leaf explants has been adapted for *Agrobacterium*-mediated transformation of *V. radiata*. The axillary meristems at the junction of the cotyledon and cotyledonary node explants contain cells most responsive for regeneration through multiple shoot induction and hence, offers suitable target for gene delivery.

Pal *et al.* (1991) employed a protocol based on shoot organogenesis from cotyledons of *V. radiata* cvs. B1 and T44 for infection with *A. tumefaciens* strains, LBA4404 harboring binary vector pBI121, and GV2260 carrying a cointegrate vector pGV2260 pSGluc1, and recovered primary transformants on kanamycin selection. Approximately 4–5% of the shoots produced on the kanamycin selection were transformed as confirmed by dot blot assay. However, large number of escapes on kanamycin selection, lack of evidence for stabilization, and inheritance of transgenes ruled out the applicability of such transformation system.

Transgenic calli were generated from primary leaf explants of *V. radiata* co-cultured with *A. tumefaciens* strain LBA4404 pKIWI105 (Phogat *et al.*, 1999). The transformed calli selected on kanamycin exhibited β -glucuronidase activity. The integration of *nptII* gene was confirmed by junction fragment analysis by Southern hybridization. However, the calli failed to regenerate to plants under tested culture conditions.

In *V. radiata*, nearly 80–100% transformation frequency of cotyledon and hypocotyls explants has been observed with *Agrobacterium rhizogenes* strain LBA9402 (Jaiwal *et al.*, 1998), but transformed tissue gave rise to roots only.

Transgenic plants of *V. radiata* cv. K-851 were successfully generated from cotyledonary nodes co-cultured with *A. tumefaciens* strain LBA4404 pTOK233 at an overall efficiency of 0.9% (Jaiwal *et al.*, 2001). The plants selected on kanamycin-containing medium were raised to maturity. Stable β -glucuronidase (GUS) expression was detected in stamens, pollen grains, and seeds of the T₀ plants. Molecular analysis of T₀ transformants revealed the integration and expression of transgenes.

Transgenic calli were recovered from primary leaves and hypocotyls explants of *V. radiata* at a transformation frequency of up to 50% using *A.*

Table 2 Current status of genetic transformation of *Vigna* species

tumefaciens strain EHA105 harboring pBingusint (Jaiwal *et al.*, 2001). Integration of foreign genes was confirmed by Southern analysis. However, the callus failed to regenerate to shoots.

Mahalakshmi *et al.* (2006) recovered transgenic plants of *V. radiata* cv. K-851 from primary leaf explants of 10-day-old seedlings, co-cultured with *A. tumefaciens* strain C58 pCAMBIA1301, on hygromycin selection medium. Molecular analysis confirmed the stable integration and inheritance of the *hpt* gene. However, absence of prolific regeneration from primary leaf explants and generation of escapes on hygromycin-containing medium may restrict the use of these explants for routine introduction of desirable genes to *V. radiata*.

Sonia *et al.* (2007) generated fertile transgenic plants of *V. radiata* from cotyledonary node explants co-cultured with *A. tumefaciens* strain EHA105 harboring a binary vector pKSB that carried bialaphos resistance (*bar*) gene and *Phaseolus vulgaris* α -amylase inhibitor-1 (α AI-1) gene. Transformed shoots were regenerated and rooted on phosphinothricin (PPT)-containing medium. Preculture and wounding of the explants, presence of acetosyringone, and PPT-based selection of transformants played significant role in enhancing transformation frequency. Expression of the *bar* gene in primary transformants were confirmed by polymerase chain reaction (PCR) analysis and PPT leaf paint assay, respectively. Integration of the α AI-1 gene was confirmed by Southern hybridization. Inheritance of both transgenes was confirmed by PCR analysis. Transgenic plants were recovered after 8–10 weeks of co-cultivation with *Agrobacterium* with a frequency of 1.51%.

Bhargava and Smigocki (1994) observed transient expression of *gus* gene in the germinated embryos of *Vigna aconitifolia*, *V. mungo*, and *V. radiata*, 18–24 h after particle bombardment. Bombarding embryos two to three times increased the level of expression up to fourfold in the explants. The plantlets were rooted on a kanamycin selection medium. However, molecular analysis was not carried out to confirm the stable expression of *gus*.

2.2 *Vigna angularis*

Reproducible transformation in azukibean (*V. angularis*) was reported using *A. tumefaciens*-

mediated gene transfer to epicotyl explants (Yamada *et al.*, 2001). Binary vectors containing the neomycin phosphotransferase II gene (*nptII*), and *gus* or the modified green fluorescent protein (sGFP(S65T)) gene were used for transformation. The combined action of acetosyringone and high concentration of benzyladenine (BA) in co-cultivation medium played important roles in improving transformation efficiency in epicotyl explants of azukibean. Further, the *Agrobacterium* strain was found to influence the transformation efficiency. AGL1 and EHA105 showed higher transformation than the strain LBA4404. AGL1 and EHA105 harbor a hypervirulent Ti plasmid and were developed to exhibit a broad host range and high transformation frequency. Molecular analysis confirmed the stable integration and expression of foreign genes. The T₀ plants produced viable seeds.

Ishimoto *et al.* (1996) introduced bean α -amylase inhibitor gene to azukibean (*V. angularis*) and generated transgenic plants resistant to the storage pest, bruchid. The bean α -amylase inhibitor gene was driven by the promoter of phytohaemagglutinin leading to high level accumulation of α -amylase inhibitor proteins in the transgenic seeds and subsequent complete block of bruchid development. The system relied on *Agrobacterium* infection of epicotyl explant and subsequent selection on kanamycin-containing medium.

The D6-fatty-acid desaturase gene isolated from *Mortierella alpina* IS-4 was introduced into *V. angularis* by *Agrobacterium*-mediated transformation and constitutively expressed (Chen *et al.*, 2005). The γ -linolenic acid (GLA) accumulated at levels of up to 0.44% and 1.26% of the total fatty acids in the leaves and seeds, respectively, of a transgenic *V. angularis* line and at 0.69% in the leaves of its progeny. These findings reveal that the modification of the fatty-acid biosynthetic pathway by genetic manipulation in order to produce specific polyunsaturated fatty acids in grain legume crops is a promising technique. The seed germination, hypocotyl culture, and genetic transformation procedures were performed using a modified version of the method of Yamada *et al.* (2001). The *A. tumefaciens* EHA105/pSPB559 vector was used for this transformation. Kanamycin-resistance callus lines were obtained on kanamycin selection after 2 months, which regenerated plantlets. The

adventitious shoots that formed on the induced calli were transferred to a rooting medium with kanamycin. The T₀ transgenic plants and their T₁ progenies grew, flowered, and produced seeds normally. Genomic Southern hybridization analysis confirmed the stable integration of transgene. The D6-fatty-acid desaturase gene was inserted multiple times into the transgenic plant genomes. The RT-PCR results indicated the transcription of D6-fatty-acid desaturase gene in transgenic lines. The fatty-acid compositions of the whole lipids extracted from the leaves and seeds of the T₀ transgenic plants and the leaves of their T₁ progenies were detected by using GC-MS. These findings reveal that modification of the fatty-acid biosynthetic pathway by genetic manipulation in order to produce specific polyunsaturated fatty acids in grain legume crops is a promising technique.

Yamada *et al.* (2005) isolated cDNAs encoding for two isoforms of α -amylase inhibitor, i.e., α AI-Pa1 and α AI-Pa2 from tepary bean (*Phaseolus acutifolius*) and expressed these cDNAs in *V. angularis*, which revealed that active forms of the inhibitor proteins accumulated in seeds and exhibited specificities for insect α -amylases identical to those of the native proteins purified from tepary bean seeds. Seeds transgenic for *ai-Pa1* thus inhibited the larval α -amylase activity of *C. chinensis* but not that of *Zabrotes subfasciatus*, whereas *ai-Pa2* transgenic seeds inhibited the larval α -amylases of both of these insects. Seed extracts of both types of transgenic plants inhibited the larval α -amylases of the cereal storage pests *Tenebrio molitor* and *Tribolium confusum* but had no effect on porcine pancreatic α -amylase. The inhibitory specificities of the transgenic azukibean seeds thus further confirmed that *ai-Pa1* and *ai-Pa2* encode α AI-Pa1 and α AI-Pa2, respectively. The active form of α AI-Pa1 in transgenic azuki bean was a single polypeptide with a size similar to that expected for the full-length encoded protein. These results suggest that α AI-Pa1 defines a new type of bean α AI that is structurally related to lectins and is not activated by proteolytic processing.

2.3 *Vigna mungo*

Urdbean production is severely limited due to its prominent susceptibility to MYMV, fungal

pathogens, and insect pests (Sahoo *et al.*, 2003). MYMV is the most devastating and widespread viral disease, which can cause complete damage to plants when infected at the seedling stage (Varma *et al.*, 1998). None of the known cultivars of *V. mungo* is fully resistant to MYMV. Genetic engineering of *V. mungo* for MYMV resistance is one of the major research mandates.

Karthikeyan *et al.* (1996) obtained transformed calli of *V. mungo* by co-cultivating segments of primary leaves with *Agrobacterium* strains LBA4404 and EHA105 carrying binary vector pGA472. Transformation frequency with LBA4404 and EHA105 was 23% and 10%, respectively. The stable integration of *nptII* gene in transformed calli was confirmed by Southern blot analysis and the expression was demonstrated by neomycin phosphotransferase assay.

The amenability of various seedling explants of *V. mungo* to *Agrobacterium* infection has been evaluated in preliminary transformation studies. Saini and Jaiwal (2002) demonstrated the competence of seedling epicotyl explants for *Agrobacterium*-mediated transformation. A highly site-specific direct shoot regeneration system was developed from the apical end of these nonmeristematic explants.

Saini *et al.* (2003) generated fertile transgenic plants from cotyledonary node explants inoculated with *A. tumefaciens* carrying binary vector pCambia2301 at a frequency of 1%. Mechanical wounding of the explants prior to inoculation with *Agrobacterium*, time lag in regeneration due to removal of the cotyledons from explants, and a second round of selection on kanamycin at the rooting stage were found to be critical for transformation. Southern analysis of T₀ plants showed the integration of *uidA* into the plant genome. Stable GUS activity was detected in leaves, roots, flowers, anthers, and pollen grains. The progenies revealed a Mendelian pattern of transgene inheritance. However, the efficiency of transformation of meristematic cells in the axil of the cotyledonary node regions was low (1%), which may be attributed to the presence of limited number of regenerable cells whose capacity for regeneration was short lived, and inefficient T-DNA delivery to the regenerable cells (Saini and Jaiwal, 2005). An *Agrobacterium*-mediated transformation of shoot apex explants was developed to overcome these limitations (Saini and Jaiwal, 2005). A significant increase in production

of transgenic plants was observed from an average of 1–6.5% when shoot apices were preconditioned with BAP, and wounded prior to their inoculation with *A. tumefaciens* strain EHA105 carrying the binary vector pCAMBIA2301. GUS activity was detected in T₀ shoots and T₁ seedlings. Southern analysis of T₁ plants showed integration of *nptII* into the plant genome. Majority of the T₀ plants transmitted transgenes in Mendelian fashion. Shoot apex is preferred because of the high regeneration potential of the pre-existing meristems, which require minimal tissue culture manipulations for rapid and direct multiple shoot induction in a less genotype independent fashion. *A. tumefaciens* strain EHA105 carrying a binary vector pCAMBIA2301, which contains a neomycin phosphotransferase gene (*nptII*) and a β -glucuronidase (GUS) gene (*uidA*) interrupted with an intron, was used for transformation of *V. mungo* cotyledonary node explants. Various factors such as preculture and wounding of explants, manipulations in inoculation and co-cultivation conditions were found to play a significant role in influencing tissue competence, *Agrobacterium* virulence and compatibility of both, for achieving the maximum transformation frequencies. The stable transformation with 4.31% efficiency was achieved using the optimized conditions. The transformed green shoots that were selected and rooted on medium containing kanamycin and tested positive for *nptII* gene by PCR were established in soil to collect seeds. GUS activity was detected in leaves, roots, pollen grains, and T₁ seedlings. Southern analysis of T₀ plants showed the integration of *nptII* into the plant genome. Saini and Jaiwal (2007) systematically optimized the conditions favorable for enhanced transformation of cotyledonary node explants and generated stable transgenic plants with an overall transformation efficiency of 4.31%. These efficient transformation systems would enable the transfer of desirable genes in future.

2.4 Assessment of Gene Delivery in *Vigna* Species

Agrobacterium-mediated transformation is more directed and stable method for introduction of a transgene due to the preferential mechanism of T-DNA insertion (Zupan and Zambryski,

1997). Owing to the natural recalcitrance exhibited by *Vigna* species to *Agrobacterium* infection, compatibility of plant regeneration system to *Agrobacterium* infection decides the success or failure in transformation.

Majority of the transformation systems developed in these species target cells of the seedling explants, which permit either adventitious regeneration or axillary shoot proliferation. They are more promisingly used for *Agrobacterium*-mediated transformation with a high degree of success and in more or less variety independent manner. The rapid regeneration of fertile plant from this tissue avoiding intermediate callus phase considerably shortens the time required to generate transgenic plants.

The system for *Agrobacterium*-mediated genetic transformation of *V. radiata* and *V. mungo* using cotyledonary node explants from young seedling has been perfected with success rate ranging from low to moderate transformation frequency. Extensive work needs to be initiated for incorporation of genes encoding desirable traits in these two Asiatic *Vigna* species using the perfected transformation system. Similar genetic transformation system targeting pre-existing meristems of young seedling of *V. aconitifolia* may lead to recovery of fertile transgenic plants.

While chances of recovery of true transgenics from dedifferentiated tissue, with a *de novo* regeneration mode, is very high; such tissue neither has been targeted nor adequately applied for *Agrobacterium*-mediated transformation except in *V. angularis* (Ishimoto *et al.*, 1996; Yamada *et al.*, 2001).

Owing to the natural resistance of many plants including legumes to antibiotics (Dekeyser *et al.*, 1990), appropriate antibiotic and its effective concentration for selection of transformants for particular *Vigna* species can only be determined empirically (Babaoglu *et al.*, 2000). The dose of selective agent (lethal or sublethal), time of its application (i.e., more precisely immediately after co-culture or at a much delayed stage), and increments (gradual increasing or decreasing increments) need to be carefully assessed for a particular species and a variety of explants. Judicious choice of selective levels has remained as an important criterion for the recovery of transformed cells at initial stage of screening (Sharma and Ortiz, 2000).

Comparison of various analogs of antibiotics for their ability to select transformants without interference in regeneration may help in deciding the suitable antibiotic for selection of transformants in *Vigna* species. The herbicide-based selection has been efficiently used both at shoot and induction level for recovery of transformants in *V. radiata* (Sonia *et al.*, 2007). Such herbicide-based selection may find useful in providing an efficient selection and enhancement of transformation frequency in related *Vigna* species.

In the case of *Agrobacterium*-mediated transformation, some strains are more effective with a particular species than others (Christou, 1994). Evaluation of strain–cultivar compatibility is an important step in the establishment of a transformation protocol. While the natural virulence of *Agrobacterium* varies and hence their ability to infect *Vigna* species, the virulence of some strains can be improved by the introduction of supervirulent plasmid carrying extra copies of key virulence genes, alongside the binary vector. Use of *Agrobacterium* strain with super binary vectors or binary vector with additional copies of *vir* genes is an important consideration in the transformation of least amenable *Vigna* species.

Vir gene activity and transformation have been shown to be affected by diverse conditions during the infection and co-cultivation stage (Stachel *et al.*, 1986; Vernade *et al.*, 1988; Godwin *et al.*, 1991; Holford *et al.*, 1992; Dillen *et al.*, 1997). These parameters are vital for achieving optimal T-DNA transfer to cotyledonary node explants in *Vigna* species (Jaiwal *et al.*, 2001; Saini and Jaiwal, 2007) although these effects may not consistent across explants and species.

The beneficial effect of preculture/preconditioning of explants on transformation has been reported in *Vigna* species (Sonia *et al.*, 2007) although it is not clear why regeneration of transgenic shoots requires a preculture period, especially in the light of the fact that no preculture period is required for cellular transformation (McHughen *et al.*, 1989). The insertion of T-DNA does not interfere with regeneration because regeneration from transformed cells does occur from precultured explant. During the preculture time, the tissues undergo a physiological and developmental shift to become competent to regenerate; when the T-DNA is inserted after such a period, the recipient cells are already

on the developmental pathway for regeneration. In such cases, if preculture is not allowed, the presence of bacteria of the selection agent perhaps interferes with the expected physiological shift in the cultured cells from nonregenerable to competent for regeneration and leads to failure of transformation.

Direct DNA delivery by particle bombardment is more promising as no specific DNA regions are required for the DNA integration, as in the case of *Agrobacterium*, thus allowing the introduction into the plant genome of only the target genes without any extra redundant plasmid DNA (Fu *et al.*, 2000). The high degree of specificity (severe species specific and frequently cultivar specific) reflected in *Agrobacterium*-mediated transformation has precluded the use of this method. Thus, particle bombardment may be the preferred option for gene introduction into grain legumes, *Vigna* species in particular, circumventing the host specificity of these species to *Agrobacterium* infection.

Shoot apical meristems of mature seeds or whole embryos have been used extensively as target tissues for particle bombardment in legumes (Kim and Minamikawa, 1996, 1997; Aragao *et al.*, 2000) and, with limited success in *V. radiata* (Bhargava and Smigocki, 1994). In majority of the cases, explants from near the shoot apex or the apex itself, have been the targets of choice (Christou, 1997) as apical meristems permit rapid regeneration of complete fertile plant with minimum culture manipulation in a variety-independent manner.

The major problem encountered with organized tissue, shoot apex in particular, is that transformed cells permit proliferation of nontransformed tissue in their vicinity by effectively detoxifying the selective agent. This results in the creation of chimeric tissue, which subsequently gives rise to both transformed and nontransformed plants, the latter being of the overwhelming majority. Although regeneration of intact plants from transformed tissue is not always an easy task, the problem can be overcome by using a highly specific selective agent that effectively mobilize to apical tissues, making selection of these remote tissues much efficient. Using imazapyr for selection of transformed shoots in combination with *ahas* gene, transgenic plants have been successfully recovered from bombarded shoot apices in common bean (Aragao *et al.*, 2000).

Although the use of particle bombardment for transformation of *Vigna* species is still at an infant stage, mostly restricted to transient GUS expression in bombarded tissue (Bhargava and Smigocki, 1994), success in generating transgenics using shoot apex-particle bombardment with subsequent highly specific selection system seems to be practical.

Electroporation-mediated gene transfer system described by Chowira *et al.* (1995, 1996) uses intact nodal meristems and relies on the plant to develop its reproductive structures from the treated apices in a more or less normal fashion. Transformation of intact embryonic explants by electroporation (Dillen *et al.*, 1995) obtained high frequency of transformation with wider applicability to diverse legume species. *In planta* techniques that does not rely on shoot production from tissues cultured *in vitro* are potentially more rapid, avoiding the complexities of cell and tissue culture, and reduce the likelihood of somaclonal variation. *In planta* techniques in conjunction with electroporation may perhaps circumvent the high recalcitrance of *Vigna* species exhibited to transformation.

3. CONCLUSION AND FUTURE PROSPECTS

The importance of *Vigna* species as a cheap source of protein is an important consideration in developing countries as the people in this region derive most of their nutritional calories from grain legumes. Although these crops occupy unique position with regard to their total area of cultivation as well as production, the yield is severely limited due to diseases (viral, fungal, insects, and storage pests) besides considerable yield loss due to drought and salinity.

In view of the severity of insect-pest related grain yield losses and the expectation of only a slow rate of progress by routine conventional breeding, transfer of ideal genes coding for the insect-specific toxins of *Bacillus thuringiensis* (*Bt*), α -amylase inhibitor for storage pests resistance (Chrispeels, 1997), chitinase, glucanase, RIP (ribosome inactivating protein) for resistance to fungal pathogens can check the damage. In the quest for resistant cultivars to multiple stresses, combining several biotechnological approaches such as transgenesis or mutagenesis and marker-

assisted selection (MAS) to pyramid multiple resistance genes appears to be a powerful strategy (Dita *et al.*, 2006). Such an approach was recently achieved in soybean to manage insect resistance, resulting in the enhancement of resistance levels to corn earworm (*Helicoverpa zea*) and soybean looper (*Pseudoplusia includens*) in eight soybean lines in which two major insect-resistance quantitative trait loci (QTLs) and a synthetic *Bt* gene (*cry1Ac*) were combined (Walker *et al.*, 2004).

Drought and salinity prevalent in Southeast Asia considerably limits the yield potential of *Vigna* species. Abiotic stresses generally involve perturbation of various cellular functions and activation of complex metabolic pathways, and are conferred by polygenic traits (Kassem *et al.*, 2004; Lee *et al.*, 2004; Popelka *et al.*, 2004). Polygenic nature together with the lack of good sources of natural tolerance makes conventional breeding strategies difficult to tackle these constraints. In plants, there is a poor understanding of most abiotic stress responses. Hence, successful use of genetic transformation strategies requires a better understanding of physiological and molecular mechanisms associated with these stresses. Recent progress achieved in nonlegume plants supports the potential use of transgenic approaches to produce stress tolerant varieties in *Vigna* (Kasuga *et al.*, 1999; Jiang *et al.*, 2004; Shou *et al.*, 2004; Umezawa *et al.*, 2004). The use of transgenic, mutagenic, and genetic approaches strongly improved the understanding of the genetic and molecular mechanisms of salinity tolerance in plants, and this will help to develop legumes including *Vigna*, with improved tolerance (reviewed in Hasegawa *et al.*, 2000; Apse and Blumwald, 2002). It was found that overexpression of a single-gene controlling vacuolar or plasma membrane Na^+/H^+ antiport protein, in transgenic *Arabidopsis*, tomato, and rapeseed provided them with a high level of salt tolerance under greenhouse conditions (Apse *et al.*, 1999; Zhang and Blumwald, 2001; Zhang *et al.*, 2001; Shi *et al.*, 2003). Similarly, manipulating expression of pea DNA Helicase45 or the glyoxalate pathways confers high salinity tolerance in tobacco (Singla-Pareek *et al.*, 2003; Sanan-Mishra *et al.*, 2005). Although transgenic plants are yet to be examined for salt tolerance in the field, recent genetic advances suggest that there are good prospects for developing transgenic

legumes with enhanced salt tolerance in the near future (Sharma and Lavanya, 2002).

Although *Vigna* species are consumed by millions of people, little research has been carried out on improving their nutritional value. Priority should be given to screening lines for high essential amino acid content, particularly methionine. Strains should be identified that contain lower levels of antinutritional factors and selections should be made to reduce their flatus potential. Quality improvement of these crops with enhanced protein production as well as correct nutritional balance is to be addressed and necessitates transfer of genes encoding methionine-rich proteins.

1. INTRODUCTION

Pigeonpea is one of the major grain legume crops grown in the tropics and subtropics. It is usually grown in rainfed areas that are prone to drought. Because of its high protein content, pigeonpea forms a significant component of the diet of the vegetarians in the semi-arid tropics (SAT). Genetic improvement of pigeonpea has received considerable attention over the years from plant breeders with the aim of increasing the grain yield and to minimize crop losses due to unfavorable environmental conditions, and attack by various pests and pathogens. Conventional plant breeding coupled with improved farm management practices have led to a significant increase in world pigeonpea production. Conventional breeding of pigeonpea has succeeded in producing short duration varieties and better cultivars with yield improvement, which are being grown in different parts of the world. Pigeonpea shows considerable yield losses due to various biotic and abiotic constraints. Though the wild accessions of pigeonpea are rich source of resistance to these constraints, the introgression of genes conferring resistance or tolerance to these stresses into cultivars is difficult due to cross-incompatibility. Linkage drag of desirable genes with undesirable

genes also complicates such breeding programs. Biotechnological approaches, such as gene transfer for enhanced disease and pest resistance offer opportunities for rapid improvement of pigeonpea. In recent years, biotechnology has emerged as one of the important tools for agricultural research. In concert with traditional plant breeding practices, biotechnology is contributing toward the development of novel methods to genetically alter and control plant development, plant performance, and plant products. Genetic engineering offers a possible solution by lowering the farm level production costs through making plants resistant to various abiotic and biotic stresses and by enhancing the product quality (i.e., by increasing the appearance of end product, nutritional content, or processing or storage characteristics). Therefore, pigeonpea improvement efforts have focused on raising the yield potential, quality characteristics, and resistance to biotic and abiotic stresses depending on the regional requirements of the crop through biotechnological approaches. This review deals with the recent advancements in pigeonpea breeding and emerging transgenic innovations that would play a significant role in the future pigeonpea improvement programs and offer many new opportunities to develop it as a new generation legume food crop.

1.1 History, Origin, and Distribution

There has been a major dispute on the possible origin of pigeonpea. Several conclusions have been made in favor of India given the presence of several wild relatives, the large diversity of the gene pool, ample linguistic evidences, a few archaeological remains, and the wide usage in daily cuisine (Van der Maesen, 1983). Pigeonpea now acclimatized in several tropical countries was cultivated in ancient Egypt, Africa, and Asia since prehistoric times. The name pigeonpea was first reported from plants used in Barbados where it was used as pigeon feed which led to the name “pigeonpea” in 1692 (Van der Maesen, 1986). The major producer of pigeonpea is India with over 100 cultivars, 2.4 million hectares cultivated and 90% of world production.

1.2 Botanical Description

1.2.1 Taxonomy

Pigeonpea, *Cajanus cajan* (L.) Millsp., belongs to the subtribe Cajaninae of the agriculturally most important tribe Phaseoleae under the subfamily Papilionoideae of the family Leguminosae and is the only cultivated food crop of the Cajaninae subtribe (Purseglove, 1988). Lackey reviewed the Phaseoleae as a group and realigned Bentham's classical classification (Bentham, 1837; Bentham and Hooker, 1865) taking into account the genera described since the last century. The tribe Phaseoleae also includes many important crops such as soybean (*Glycine max* L.), common bean (*Phaseolus vulgaris* L.), and mungbean (*Vigna radiata* L. Wilczek) (Young *et al.*, 2003). Pigeonpea has a diploid genome comprising 11 pairs of chromosomes ($2n = 22$) (Greilhuber and Obermayer, 1998). Karyotype analysis of both mitotic and meiotic chromosomes of pigeonpea, various wild species, and their interspecific hybrids indicated high homology and almost complete meiotic pairing.

Among the members of Phaseoleae, Cajaninae is well distinguished by the presence of vesicular glands on the leaves, calyx, and pods. Currently, 11 genera remain under Cajaninae, including *Rhynchosia* Lour, *Eriosema* DC., *G. Don*, *Dunbaria*, *W. & A.* and *Flemingia* Roxb. ex Aiton. The mem-

bers of the earlier genus *Atylosia* closely resemble the genus *Cajanus* in vegetative and reproductive characters. However, they were relegated to two separate genera mainly on the basis of the presence or absence of a seed strophiole. In 1986, Van der Maesen revised the taxonomy of *Cajanus* and merged the two genera under *Cajanus* following systematic analysis of morphological, cytological, and chemotaxonomical data, which indicated the congenicity of the two genera. *Cajanus* is now recognized as having 32 species most of which are found in India and Australia. Wild *Cajanus* species exist mostly as remnants of cultivations and persist in forests in several places. The closest wild relative, *Atylosia cajanifolia* Haines, has been found in some localities in East India and most other *Atylosias* are found scattered throughout India. In Africa, *Cajanus kerstingii* grows in the drier belts of Senegal, Ghana, Togo, and Nigeria. Pigeonpeas occur throughout the tropical and subtropical regions, as well as the warmer temperate regions (as North Carolina) from 30°N to 30°S (Duke, 1981).

Pigeonpea is divided into two botanical varieties “var. *flavus*” and “var. *bicolor*”. The cultivars of var. *flavus* are earlier maturing, have shorter plants with yellow standards, and green glabrous pods, which are light colored when ripe, and are usually three seeded. These are the *tur* cultivars of India, where they are extensively cultivated in the Peninsula. The cultivars of var. *bicolor* are perennial, late maturing, large, bushy plants, with dorsal side of standard red or purple or streaked with these colors, and hairy pods blotched with maroon or dark colored, with 4–5 seeds, which are darker colored or speckled when ripe. These are the *arhar* cultivars of India, which are more extensively cultivated in the north of the country (Purseglove, 1988).

1.2.2 Plant habit and morphology

Among the grain legumes only the pigeonpea has not been subjected to a radical change in life form. Pigeonpea is an erect perennial legume shrub often grown as an annual, attaining height of up to 5 m. Pigeonpea is almost exclusively grown as an annual, in rows and/or mixed with any other crops such as cotton, sorghum, millets, and groundnut, which are harvested several months

prior to pigeonpea. The pigeonpea plants are cut down when most of their pods have ripened, often when green leaves are still present. Spreading forms are preferred for filling the gaps formed by earlier harvested intercrop. Erect cultivars may be useful for intercropping with other crop species of similar duration, but have not proved better than spreading ones.

Pigeonpea leaves are trifoliate, green, and pubescent above and silvery grayish-green with longer hairs on the underside and spirally arranged on the stem. While the pigeonpea seedlings emerge 2–3 weeks after sowing (Duke, 1981), the vegetative growth begins slowly and accelerates at 2–3 months. Flowers occur in terminal or axillary racemes and are 2–3 cm long (Purseglove, 1968), usually yellow, but can be flocked or streaked with purple or red. Pods are flat, usually green in color, sometimes hairy, sometimes streaked, or colored dark purple, with 2–9 seeds/pod. Seeds are, widely variable in color, 6–9 mm in diameter, and weigh 4–25 g/100 seed (Sheldrake, 1984). Roots are thin with a deep-rooting taproot reaching up to 6 ft. (2 m) in depth. This deep-rooting system helps to improve water infiltration into the soil.

1.2.3 Climatic and soil requirements

Pigeonpea needs moist and warm weather during germination (30–35 °C), 20–25 °C during active vegetative growth, and about 15–18 °C during flowering and pod setting; however, at maturity it needs higher temperature of around 35–40 °C. Waterlogging, heavy rains, frost are very harmful for the crop (Chauhan, 1987). Hailstorm or rain at maturity damages the entire crop. The crop may be grown on any type of soil but sandy-loam to clayey-loam soils are supposed to be best. Soil must be very deep, well drained, and free from soluble salts.

1.2.4 Ecology

Pigeonpea is hardy, widely adaptable, and more tolerant of drought and high temperatures than most other crops. It grows best at a soil pH of 5.0–7.0, but tolerates a wider range (4.5–8.4). It grows on acid sands in the Sahel and alkali clays

in India. Ranging from warm temperate moist to wet through tropical desert to wet forest life zones, pigeonpea has been reported to tolerate annual precipitation of 5.3–40.3 dm (mean of 60 cases 14.5 dm), annual mean temperature of 15.8–27.8 °C (mean of 60 cases = 24.4 °C), and pH of 4.5–8.4 (Duke, 1981). The traditional varieties of pigeonpeas grown by farmers in India in the early 1970s were photoperiod sensitive medium- to long-season types.

1.3 Economic Importance

Pigeonpea plays an important role in food security, balanced diet, and alleviation of poverty because it can be used in diverse ways. Pigeonpea seed contains 20–30% protein, is rich in essential amino acids, carbohydrates, and minerals (Faris *et al.*, 1987; Saxena *et al.*, 2002), and is the principal source of dietary protein for an estimated 1.1 billion people, most of whom are vegetarian and poor (Jones *et al.*, 2004). Pigeonpea contains approximately 57.3% carbohydrates in dried seed. The protein and carbohydrate composition of Indian split dal is 22.3% and 57.2%, respectively (Purseglove, 1988). The crop can be described as unique because it is a legume and a woody shrub. Pigeonpea is grown for its seed for human consumption and for income generation by trading surpluses in local and commercial markets. Besides its main use as dal (dry, dehulled, split seed used for cooking), the green seeds are cooked as a vegetable in Africa, Central America, and the states of Gujarat and Karnataka in India, tender pods are cooked whole in Brazil, Thailand, and the eastern islands of Indonesia. Green peas are processed for canning and freezing in Central America and India for export to North America. The seed husks, pod walls, and green leaves are commonly fed to cattle. Branches and stems can be used for making baskets and as fuel. Pigeonpea is also used as a shade crop and wind break (young coffee, forest seedlings), cover crop, or as support (vanilla) (Duke, 1981). It has an inherent ability to withstand environmental stresses (especially drought) due to the fast growing, deep, extensive root system making it one of the most sought after crops in plant introduction trials aimed at bringing new areas under cultivation (Okiror, 1986). The slow growth of the plant above ground during

its early phase offers very little competition to other crops and allows productive intercropping with virtually any crop. It is grown as a sole crop or as an intercrop mixed with cereals (maize, sorghum, pearl millet, finger millet), fiber, and other legume crops (groundnut, soybean) under wide climatic conditions in rainfed low-input agricultural systems. Pigeonpea adapts to different climates and soils except those that are excessively wet or experience frost (Troedson *et al.*, 1990). The effect of pigeonpea on soil fertility has been studied in detail (Ong and Daniel, 1990). It contributes to the C, N, and P economy of the soil (Kumar Rao *et al.*, 1987; Rego and Nageswara Rao, 2000; Fujita *et al.*, 2004), enhancing its performance even under marginal input. Pigeonpea is tolerant to low P supply and acid soils as well as having a high capacity for incorporation of external P into organic P (Fujita *et al.*, 2004). Its critical requirement of P concentration for dry matter production is low compared to other major protein crops like soybean (Adu-Gyamfi *et al.*, 1990). This benefits both the pigeonpea crop and subsequent crops in rotation, thus contributing to increased productivity and soil amelioration (Duke, 1981; Ae *et al.*, 1990). Pigeonpea is also used to restore soil fertility and to prevent soil erosion (Al-Nahidi *et al.*, 2001; Xuxiao *et al.*, 2002). Morton (1976) listed many folk medicinal uses of pigeonpea. Dry roots, leaves, flowers, and seeds are used in different countries to treat a wide range of ailments of the skin, liver, lungs, and kidney. Because pigeonpea is a low-input rainfed crop with characteristics that provide economic returns from each and every part of the plant, its cultivation has a direct bearing on the overall economic and financial well being, and on the nutritional status of subsistence farmers in the Asian subcontinent.

A good crop of 1ha gives about 25–30 quintals of grains and about 50–60 quintals of sticks and 10 quintals of dried leaves in the form of straw. In India, pigeonpea is mainly cultivated by small and marginal farmers, accounting for 85–90% of the world's area under pigeonpea cultivation. Although, in India, there has been a considerable increase in the area under pigeonpea cultivation from 2.18 to 3.82 mha⁻¹, and the production from 1.72 to 2.88 million tons between 1950–1951 and 1996–1997, there was a significant drop in productivity from 780 to 753 kg ha⁻¹ during the same period (AICPIP, 1999). Andhra Pradesh

accounts for 10.2% of area and 4.26% of the pigeonpea production in the country. Globally, pigeonpea has recorded a 43% increase in area since 1970. It is currently grown on 4.3 m ha⁻¹. India is the largest producer with 3.2 m ha, followed by Myanmar (580 000 ha), China (60 000 ha), and Nepal (28 000 ha). In Asia, between 1972 and 2003, pigeonpea recorded 57% increase in area (2.44–3.81 m ha⁻¹) and 61% increase in production (1.72 to 2.77 million tons). In Africa between 1972 and 2003, pigeonpea recorded 66% increase in area (0.26–0.42 m ha⁻¹) and 96% increase in production (0.13 to 0.26 million tons) (<http://www.icrisat.org/PigeonPea/PigeonPea.htm>). Pigeonpea is now reported to be grown in 50 countries of Asia, Africa, and the Caribbean. The current global annual production of pigeonpea is valued at more than US\$ 1700 m (FAOSTAT, 2005).

1.4 Constraints to Pigeonpea Productivity

The production of pigeonpea has remained static over the last several years (Souframanien *et al.*, 2003). The yield on farmers' fields is low due to a number of factors. A large variation is seen in productivity across years as farmers continue to grow their traditional landraces that frequently suffer from several biotic and abiotic stresses due to lack of quality seed. Poor production practices such as low plant densities, low soil fertility, insufficient weeding, and insufficient/inappropriate use of fungicides and herbicides are other constraints. Environmental (frequent droughts, easily erodible soils with poor waterholding capacity) and socio-economic (lack of roads, marketing infrastructure, and exploitation by middlemen) factors also affect productivity. Apart from these, biotic and abiotic are the most important constraints for pigeonpea production and are listed below.

1.4.1 Biotic factors

Biotic stresses due to fungus, bacterial, and viral diseases, and insects pests cause heavy losses in yield of pigeonpea. Fungal diseases involving 45 pathogens are known in pigeonpea and the most important and widespread disease is wilt (*Fusarium udum*), favored by soil temperatures

of 17–20°C. It affects the plants at all stages of its development and in India it causes a loss of 5–20% and in severe case upto 50% loss is observed. *Fusarium* wilt is especially prevalent in India and East Africa, where field losses of over 50% are common (Marley and Hillocks, 1996). Other fungi include: *Cercospora indica* (leaf spot), *Colletotrichum cajanae*, *Corticium solani*, *Diplodia cajani* (stem canker), *Leveillula taurica*, *Macrophomina phaseoli*, *Phaeolus manihotis*, *Phoma cajani*, *Phyllosticta cajani*, *Phytophthora cajani* (stem blight), *Rhizoctonia bataticola*, *Rosellinia* spp., *Sclerotium rolfsii*, and *Uredo cajani* (rust). So far, economic damages by these have been small or negligible, but rust is locally of some importance. Pigeonpea is also attacked by the bacterium *Xanthomonas cajani* that causes leaf spot and stem canker diseases (Kay, 1979). The sterility mosaic disease caused by sterility mosaic virus is being recognized as a serious economic threat as it can cause complete crop failure (Kay, 1979).

Nematodes that are of minor importance are *Helicotylenchus cavevessi*, *H. dihytera*, *H. microcephalus*, *H. pseudorobustus*, *Heterodera* spp., *H. cajani*, *H. trifolii*, *Hoplolaimus indicus*, *Meloidogyne hapla*, *M. incognita acrita*, *M. javanica*, *M. javanica bauruensi*, *Pratylenchus* spp., *Radopholus similis*, *Rotylenchulus reniformis*, *Scutellonema bradys*, *Scutellonema clathricaudatum*, *Trichodorus mirzai*, *Tylenchorhynchus brassicae*, *T. indicus*, *Xiphinema campinense*, and *X. ifacolum*. Damage caused by insect pests is a major constraint on yield in most areas. The podborer, *Helicoverpa armigera*, is commonly regarded as the key pest throughout Africa and Asia. It is particularly damaging on early formed pods. In many parts of India, the podfly, *Melanagromyza obtusa*, takes over as the dominant pest later in the season. In some areas, a newly recognized hymenopteran pest, *Tanaostigmodes*, can also cause extensive pod damage late in the season. Pests, which can be locally or seasonally important, are plume moth (*Exelastis atomosa*), blue butterfly (*Euchrysops cnejus*), leaf tier (*Eucosma critica*), bud weevil (*Ceutorhynchus aspurulus*), spotted pod borer (*Maruca testulalis*), pea pod borer (*Etiella zinckenella*), and bugs (*Clavigralla* spp.). A blister beetle (*Mylabris pustulata*), which destroys flowers, can be a spectacular but localized pest (Kay, 1979).

Thrips (*Frankliniella schultzei*, *Megalurothrips usitatus*) may cause premature flower drop. In general, the determinate (clustering) plants lose more to lepidopterous borers while podfly causes more damage to the later indeterminate cultivars.

1.4.2 Abiotic stresses

Drought, cold heat, and salinity are the abiotic stresses that affect the pigeonpea yield. In India pigeonpea is grown predominantly in the states of Uttar Pradesh, Gujarat, and Maharashtra, which together contribute about 85% of the total growing area and production of India (Muller *et al.*, 1990). More than 51% of the saline soils in India are located in these states (Agarwal *et al.*, 1976). Among cultivated legumes, pigeonpea is classified as moderately sensitive to salinity (Keating and Fisher, 1985). Waterlogging, heavy rains, frost are very harmful for the crop. Hailstorm or rain at maturity damages the entire crop.

1.5 Pigeonpea Breeding

Many traditional breeding tools including selection, hybridization, mutation, and polyploidy, have been employed in pigeonpea improvement and some of them have been successful in improving the crop. Development of extra-early varieties and resistance to drought and waterlogging were identified as important breeding targets. Pigeonpea produced by resource-poor farmers is more vulnerable to attack by disease and insect pests and to abiotic stresses. To combat these stresses usage of pesticides, fertilizers, and irrigation are a common practice. Utilization of such inputs, however, can seriously reduce profitability and threaten the environment, and many pests are not effectively controlled with chemicals. Thus, across farming systems, biotic and abiotic stresses continue to represent the major constraints on subsistence production and economic yield of pigeonpea. Development of cultivars with improved resistance to biotic and abiotic stresses is a primary goal of pigeonpea breeding programs throughout the world. Some of the conventional breeding methods employed in pigeonpea improvement are delineated below.

1.5.1 Wide hybridization

In any crop improvement program, the parents used in the hybridization are generally different varieties of the same species. Hybrids produced from intervarietal crosses possess maximum fitness value and are favored under both nature and domestication. But, in many cases, it may be desirable or even necessary to cross individuals belonging to two different species or genera. Wide crosses or more precisely interspecific and intergeneric hybrids do not occur naturally and are eliminated by the natural forces because of nonviability and/or sterility of the hybrids. In certain crops, plant breeders in the 20th century have increasingly used interspecific hybridization for transfer of genes from a noncultivated plant species to a crop variety in related species. Distant hybridization is mostly aimed at introducing new genetic variability or to achieve a new genomic constitution in such a way that the characters of the parental species are recombined effectively. These possibilities are directly related to the degree of genetic relatedness between the parents, i.e., the closer the genome relationship between the cultivated and the wild species the greater the amount of genetic recombination, and consequently variability. Valuable characters present in wild species that can be utilized in improvement of pigeonpea cultivars and the attempts made to transfer them to cultivars are reviewed hereunder.

Interspecific hybridization in *Cajanus* species dates back to 1956 when Deodikar and Thakur (1956) made the first cross between *C. cajan* with *C. lineatus* and obtained fertile hybrids. Roy and De (1967) obtained a hybrid between *C. cajan* and *C. scarabaeoides*. The prospects of potential gene transfer for pod borer resistance, drought resistance, high fruit set, higher seed protein content, early maturity, etc., from some *Atylosia* and *Cajanus* species have been observed (Pundir and Singh, 1987).

Pundir and Singh (1987) obtained fertile hybrid from the crossings of *Atylosia cajanifolius* with the cultivated varieties, Pant A2 and UPAS 120. Considering the value of the traits, namely, leaf spot resistance, pod fly resistance, seed size, and high methionine content possessed by *Cajanus cajanifolius*, crosses involving this species might throw useful segregants in advanced generations.

Similarly, *Cajanus scarabaeoides* another species of the secondary gene pool, tolerates drought and exhibits mechanical resistance and antibiosis to *Helicoverpa* in its pods. This species can easily be crossed with pigeonpea. The high protein content (28.3%) in some accessions of this species has been transferred to pigeonpea (Saxena *et al.*, 1997). Studies carried out by Dodia *et al.* (1996) revealed that larval and pupal mass of *Helicoverpa* fed on wild pigeonpea flowers and F₁ hybrids of *C. scarabaeoides* and cultivated *C. cajan* were significantly lower than those for larvae fed on the cultivated pigeonpea indicating the scope of transferring of resistance from this wild species to the cultivated pigeonpea. Unfortunately, there has not been much success in crosses between cultivated *C. cajan* and *Cajanus sericeus*. *C. sericeus* is known for high fruit set, 5–6 seeds per pod, drought tolerance, pod borer resistance, and high seed protein content. Ariyanayagam *et al.* (1993) noted poor success when *C. sericeus* was taken as maternal parent of crosses with pigeonpea as it produced male sterile lines having mitochondria of the *C. sericeus*. Another species of secondary gene pool having salinity tolerance is *Cajanus albicans* (Subbarao, 1988). Kumar *et al.* (1985) obtained 7% success, when *C. cajan* was taken as a female in crosses with *C. albicans*. Whereas, Ariyanayagam *et al.* (1993) noted that crosses of *C. albicans* with pigeonpea with latter as male parent resulted in high level of male sterility in F₁ generation (Table 1).

Cajanus acutifolius, a species of Australian native, belongs to the secondary gene pool. It is drought tolerant and crossable with pigeonpea. Fertile seeds were not formed in hybrids when *C. acutifolius* was used as female parent (Ariyanayagam *et al.*, 1993). *Cajanus platycarpus* is the only species of tertiary gene pool that has a great potential donor traits including resistance to *Fusarium* wilt (*F. udum*) and *Phytophthora* blight (*Phytophthora drechsleri* f. sp. *cajani*) diseases, high pod set and large seed size (Pundir and Singh, 1987), and salinity tolerance (Subbarao, 1988). Ariyanayagam and Spence (1978) reported successful hybrids between *Atylosia platycarpus* and pigeonpea, and suggested that genes for earliness and insensitivity to day length could be transferred from *A. platycarpus* in to pigeonpea.

Table 1 Wide hybridization and important traits in wild species of pigeonpea

Wild species	Useful characters	Remarks	References
<i>C. scaraboides</i>	Drought tolerant, mechanical resistance, and antibiosis to <i>Helicoverpa</i> , high protein content (28.3%)	High protein content transferred to pigeonpea, larval and pupal mass reduced when fed on F ₁ hybrids	Dodia <i>et al.</i> , 1996
<i>C. sericeus</i>	High fruit set, 5–6 seeds/pod, drought resistant, pod borer resistant, high protein content (28.6%)	Male sterile hybrids with <i>C. sericeus</i> as maternal parent	Ariyanayagam <i>et al.</i> , 1978; Wanjari, 1998
<i>C. albicans</i>	Sterility mosaic resistant, high seed protein content (28.7%), salinity tolerance	7% success in crosses with <i>C. cajan</i> as female parent, male sterility in F ₁ hybrids with <i>C. cajanus</i> as male parent	Kumar <i>et al.</i> , 1985; Subbarao, 1988; Ariyanayagam <i>et al.</i> , 1978
<i>C. acutifolius</i>	Drought tolerant, sterility mosaic resistant, high seed protein content (28.7%)	Male sterile F ₁ hybrids with both <i>C. cajanus</i> as female and male parent	Ariyanayagam <i>et al.</i> , 1978
<i>C. platycarpus</i>	Resistant to <i>Fusarium</i> wilt and <i>Phytophthora</i> blight, early maturity and annuality, high pod set and large seed size, high protein content (29.3%) salinity tolerance	F ₁ hybrids were produced, F ₁ hybrid with under developed seeds, reciprocal pollination using <i>C. platycarpus</i> as male parent was unsuccessful	Ariyanayagam and Spence, 1978; Saxena <i>et al.</i> , 1996
<i>C. cajanifolius</i>	Leaf spot and pod fly resistant, high methionine content, high protein content (29.2%)	Fertile F ₁ hybrids, semi-fertile F ₁ hybrids with forage potential, high protein content in F ₁ hybrids	Pundir and Singh, 1987

1.5.2 Heterosis breeding

Heterosis is the superiority in the performance of hybrid over both the parents. Commercial exploitation of heterosis in crop plants is regarded as a major breakthrough in the realm of plant breeding. It has led to considerable yield improvement of several cereals and other crops (Rai, 1979). Exploitation of “hybrid vigor” or “heterosis” showed a quantum jump in yields in some cereals and vegetable crops in the past. In legumes, this system could not be exploited for enhancing the productivity, primarily due to their cleistogamous nature of flowers that do not permit economical mass pollen transfer, necessary for large-scale hybrid seed production (Saxena *et al.*, 1997). Pigeonpea, however, is an exception where insect-mediated natural outcrossing up to 70% has been reported (Saxena *et al.*, 1990). Solomon *et al.* (1957) were the first to report hybrid vigor in pigeonpea for yield as 24.5%. The availability

of cytoplasmic male sterility (CMS) in this crop (Tikka *et al.*, 1997; Wanjari *et al.*, 2001; Saxena and Kumar, 2003) has opened up the possibilities of developing commercial hybrids. The discovery of stable male sterility systems, availability of natural outcrossing, and evidence of yield advantage has set a perfect stage for increasing yield through developing high yielding widely adapted hybrids to break the persisting yield plateau in pigeonpea.

Male sterility is the inability of a bisexual flower to produce functional male gamete or viable zygote attributed to nuclear genomic origin (genomic male sterility) (g mst; Ariyanayagam *et al.*, 1993) or to nuclear and cytoplasm factors (cytoplasmic-genetic male sterility, g-c mst). Reddy *et al.* (1978) made the first serious attempt at ICRISAT to search a male sterile system that could be used in hybrid production technology. In pigeonpea, two types of g mst, namely, ms1 (Reddy *et al.*, 1978) and ms2 (Saxena *et al.*, 1983) were found and are governed by single

recessive genes. The inheritance of g-c mst is non-Mendelian, as the transfer of cytoplasm is through the maternal parent. In pigeonpea, natural outcrossing was noticed as early as 1919 (Howard *et al.*, 1919) but its utilization in commercial hybrid breeding program was ruled out (Singh *et al.*, 1974) mainly due to the nonavailability of male sterility. With the identification of g mst and g-c mst commercial utilization of the heterosis in pigeonpea was possible. In pigeonpea, male sterility can be induced through crosses, through chemicals such as streptomycin sulfate (SS), sodium azide (SA), Terramycin, ethylmethane sulfonate (EMS), through γ -rays, and through wide hybridization.

Hybrids produced using genetic male sterile lines were not successful on a commercial scale because of high labor costs and skill requirements among seed producers. This drawback was overcome by CMS-based hybrid production introduced by ICRISAT. The CMS technology involves crossing the wild relative of pigeonpea with the cultivated variety and producing cytoplasmic male sterile plant through backcrosses. The male sterile progeny resulting from this cross is then crossed with other fertile restorer lines, resulting in all fertile offspring. CMS-based hybrids produce 30% more root mass than other varieties, which was a significant achievement in case of pigeonpea as it is a semi-arid crop (Saxena *et al.*, 2005).

Experimental hybrids developed by using CMS lines have demonstrated a yield advantage of over 25% (Saxena, 2004). It is a known fact that for a long-term commercially viable hybrid breeding program both genetic as well as cytoplasmic diversity are essential. For utilizing this new CMS source in a practical hybrid pigeonpea breeding program, the male sterility maintainers need to be identified among the cultivated types and this can be achieved by crossing a number of genetically diverse pigeonpea lines with the male sterile genotypes that should be followed by backcrossing and selection.

The magnitude of heterosis in pigeonpea is more or less similar to those of other crops such as maize, cotton, rice, millet, and sorghum (Saxena, 2004). Heterosis in pigeonpea could be exploited commercially if a grower-friendly mass-scale hybrid seed production technology is developed. So far, four wild relatives of pigeonpea have been successfully used to breed CMS systems

for developing commercial hybrid pigeonpea breeding technology. These are: *C. sericeus* (Benth. ex Bak.) van der Maesen comb. nov. (Saxena *et al.*, 2002), *C. scarabaeoides* (L.) Thou. (Tikka *et al.*, 1997; Saxena and Kumar, 2003), *Cajanus volubilis* Blanco (Wanjari *et al.*, 2001), and *C. cajanifolius* (Haines) Van der Maesen comb. nov. (Saxena, 2004). Very recently, Saxena *et al.* (2005) reported a new source of CMS developed by using the cultivated pigeonpea as the female parent and one of its wild relative *C. acutifolius* as the pollen donor and it is the first report in pigeonpea where CMS has been developed using the cytoplasm of cultivated pigeonpea.

So far four pigeonpea hybrids based on genetic male sterility were released in India and they are as follows:

ICPH 8: The world's first pigeonpea hybrid ICPH 8 (MS Prabhat DT \times ICPL 169) was released by ICRISAT and ICAR in 1991. ICPH 8 was superior to controls UPAS 120 and Manak by 30.5% and 34.2%, respectively.

PPH 4: It was released in 1993 by Punjab Agricultural University (PAU), Ludhiana (Verma and Sindhu, 1995). PPH 4 (MS Prabhat DT \times AL 688) recorded 32.1% higher yield than the best national check, UPAS 120. These early maturing pigeonpea hybrids with high yield potential are highly suitable for pigeonpea-wheat cropping system in the irrigated areas of northern India.

COPH 1 and COPH 2: In 1994, a short-duration hybrid IPH 732 (MST-21 \times ICPL 87109) was released by Tamil Nadu Agricultural University (TNAU), Coimabtoire as COPH 1 that recorded 32% higher yield over control VBN 1 (Murugarajendran *et al.*, 1995). In 1997, TNAU released another pigeonpea hybrid COPH2 (Ms CO 5 \times ICPL 83027), which outyielded COPH 1 and CO 5 by 13% and 35%, respectively.

AKPH 4104 and AKPH 2022: They were released by Punjabrao Krishi Vidhyapeeth, Akola. AKPH 4104, released for central zone, is a short-duration hybrid gave 64% higher yield than control UPAS 120. AKPH 2022 is a medium-duration hybrid released for Maharastra state that recorded 34.9%, 28.2%, and 25.2% more yields than controls BDN 2, C 11, and ICPL 87119, respectively.

At ICRISAT, three CMS lines are being maintained. They are CMS 85010, a short-duration line with determinate growth habit; CMS 88034 is a nondeterminate short-duration type while CMS 13092 has genome from African germplasm and it belongs to long-duration group.

1.5.3 Embryo rescue

Wild relatives of crop plants comprise an important germplasm resource for plant improvement (Davey *et al.*, 1994). Crosses between distantly related plants are generally unfruitful because of the abortion of embryos on the mother plant. These embryos can be precociously excised and cultured *in vitro* (Monnier, 1990). By using this technique, a large number of hybrid plants have been obtained and several genetic characteristics have been transferred in grain legumes, such as hybrids produced in *Arachis* (Bajaj, 1990) and *Glycine* (Grant, 1990).

Mallikarjuna *et al.* (2006) reported successful generation of backcross progeny by the use of *in vitro* techniques and conventional backcross program. This is the first report in pigeonpea where an incompatible wild species from tertiary gene pool, such as *C. platycarpus*, has been successfully crossed with cultivated pigeonpea and fertile hybrids and backcross progeny obtained. When using wild species from the tertiary gene pool, it is usually necessary to use embryo rescue techniques at least once to obtain hybrid plants. But in pigeonpea using embryo rescue method twice, and increasing the ploidy ($2n = 44$) hybrids were produced between the incompatible cross of *C. platycarpus* with cultivated *C. cajan*. The study shows that it is possible to transfer important traits such as resistance to phytophthora blight from *C. platycarpus*, although it is distantly related to cultivated pigeonpea.

2. TRANSGENIC PIGEONPEA

The genetic transformation of pigeonpea plants involves the stable introduction of functional genes into the nuclear genome of cells capable of giving rise to a whole plant. Despite significant advances over the past decade, the development of efficient transformation methods can take many

years of painstaking research. Transformation efficiencies, frequently, are directly related to the tissue culture responses and therefore, highly regenerative cultures are often transformation competent. Direct regeneration is preferred to indirect regeneration as the length of callus phase is negatively correlated with regeneration ability, where the somaclonal variation can also influence phenotype of the regenerated shoots (Fontanna *et al.*, 1993). In pigeonpea only few reports are available on genetic transformation and they are reviewed here.

2.1 Donor Genes

Gene cloning is the process of isolation and multiplication of an individual gene sequence by insertion of that sequence into a bacterium where, it can be replicated. Vectors used in cloning have been specially developed by adding certain features like: reduction in size of vector to a minimum; introduction of selectable markers and synthetic cloning or polycloning sites; incorporation of axillary sequences, etc. The genetic transformation generally involves two genes, namely, transgene that should be integrated in plant genome and expressed in the transgenic plant and the other is selectable marker gene. Each of the two transgenes should thus have their own promoter and termination sequences.

For producing pigeonpea transgenics for insect resistance, Lawrence and Koundal (2001) used the binary vector construct (pCPI) cloned in Bin19 having the cowpea protease inhibitor gene. Similarly, transgenic pigeonpea plants for oral vaccines were produced by using the recombinant binary vector pBI H carrying the *hemagglutinin* gene (*H*) for rinderpest virus and peste des petits ruminants virus (PPRV) under the control of a cauliflower mosaic virus (CaMV 35S) promoter and *nos* polyadenylation sequence, and *nptII* as a marker gene under the control of the *nos* promoter and polyadenylation sequences (Satyavathi *et al.*, 2003; Prasad *et al.*, 2004). Here, the *H* gene was cloned initially in pBI 121 by replacing the *uidA* gene and mobilized to EHA 105 *Agrobacterium* strain. Pigeonpea transformation for disease resistance has been carried out with a disarmed C-58 strain of *Agrobacterium tumefaciens* harboring a binary plasmid pCambia 1302: *RChit* (Kumar

et al., 2004b). Here, a rice chitinase (*Rchit*) gene driven by CaMV 35S promoter and a CaMV 35S poly-A sequence was subcloned into pCAMBIA 1302 vector to produce a pCAMBIA 1302:*Rchit* binary plasmid. It also contained the hygromycin phosphotransferase (*hpt*) gene (used as a selectable marker) and the green fluorescent protein (*gfp*) gene (used as reporter gene) under the control of CaMV 35S promoter and CaMV 35S poly-A sequences.

Surekha *et al.* (2005) used the hybrid endotoxin CryIE-C by replacing 530–587 amino acid residues of CryIEa protein with 70 amino acid region of CryICa in domain III for pigeonpea transformation. The binary vector pPK 202 carried the *cryIE-C* and *nptII* genes driven by CaMV 35S promoter and *nos* polyadenylation sequence. Very recently, Sharma *et al.* (2006a) also reported pigeonpea transformation using *Bt cryIAb* gene cloned into the binary vector pHS723 by blunt end ligation, where CaMV 35S promoter and polyadenylation sequence had driven the *cryIAb* gene. The plasmid also contained fused *uidA* and *nptII* genes as reporter and marker genes, respectively. These genes were driven by double enhanced CaMV 35S promoter and poly-A sequence.

2.2 Methods of Genetic Transformation

Transformation of plants involves the stable introduction of DNA sequences usually into the nuclear genome of cells capable of giving rise to a whole transformed plant. Transformation without regeneration and regeneration without transformation are of limited value. Transformation in pigeonpea has been feasible using both *Agrobacterium* and biolistics mode of transformations but transgenic plant targeting a trait has been produced only using *Agrobacterium* mode of transformation. *A. tumefaciens* is a soil-borne bacterium that has been implicated in gall formation at the wounded sites of many dicotyledonous plants. To date, numerous strains of *A. tumefaciens* have been isolated and characterized, but only a few of these have been modified for use in the transformation of higher plants (Muthukumar *et al.*, 1996; Jaiwal *et al.*, 1998; Yan *et al.*, 2000; Krishnamurthy *et al.*, 2000).

The recent developments in genetic transformation in pigeonpea have emboldened researchers to

pursue the development of transgenic pigeonpea plants resistant to various diseases, and insect pests (Satyavathi *et al.*, 2003; Kumar *et al.*, 2004b; Surekha *et al.*, 2005; Sharma *et al.*, 2006a). In most of the available reports in transformation of pigeonpea (Arundhati, 1999; Geetha *et al.*, 1999; Satyavathi *et al.*, 2003; Kumar *et al.*, 2004a, b), co-cultivation for 48 h in nonselective shoot regeneration medium proved good. However, Sharma *et al.* (2006a) reported that co-cultivation of the axillary meristem explants for 72 h was useful in obtaining a high frequency of stable transformants. The *Agrobacterium* strains that have been successfully used for pigeonpea transformation are based on chromosomal backgrounds of strains LBA4404 and C58 with a wide range of Ti and binary plasmids. Strains such as LBA4404, C58, EHA105, GV3101, and GV2260 and binary vectors like pBI121, pCAMBIA1301, pBAL2, and pHS723 were used in *Agrobacterium*-mediated transformation of pigeonpea (Arundhati, 1999; Geetha *et al.*, 1999; Lawrence and Koundal, 2001; Satyavathi *et al.*, 2003; Prasad *et al.*, 2004; Kumar *et al.*, 2004a, b; Singh *et al.*, 2004; Sharma *et al.*, 2006a, b).

Factors like growth phase of the *Agrobacterium* culture, co-cultivation medium, time period of co-cultivation, temperature during co-cultivation, addition of *vir*-inducing chemicals in the medium, promoters, and explants used etc. effects the *Agrobacterium*-mediated genetic transformation in pigeonpea. Addition of chemicals that induce *vir* genes in co-cultivation media is common practice in genetic transformation of many crop species especially monocots, however, the liberation of phenolic compounds by the explant itself is enough to favor the *Agrobacterium* infection in pigeonpea (Sharma *et al.*, 2006a).

Although, pigeonpea was considered to be recalcitrant for long, recent reports on its genetic transformation with convincing molecular evidence indicates that the *Agrobacterium*-mediated genetic transformation is feasible in pigeonpea. Lawrence and Koundal (2001) have used *Agrobacterium* strain GV2260 carrying the *nptII* and cowpea protease inhibitor genes on a binary vector to infect the embryonal axes of pigeonpea and obtained multiple shoots following callus proliferation on Murashige and Skoog (MS) medium supplemented with 6-benzylaminopurine (BAP) (2 mg l⁻¹) and indole 3-acetic acid (IAA)

(0.2 mg l⁻¹) using this method a transformation frequency of less than 1% was obtained. Following this, Satyavathi *et al.* (2003) reported the successful recovery of pigeonpea transgenics for protective *H*-antigen gene (Haemagglutinin gene) through direct regeneration of cotyledonary node and embryonic axis after infecting with the virulent strain EHA105 of *A. tumefaciens* that harbored the binary plasmid pBI121 carrying the *H* antigen of rinderpest virus and *nptII* genes. The bacterial culture at late log phase with an O.D. 0.6 at 260 nm and a co-cultivation period of 48 h was used in this study. Similarly, Prasad *et al.* (2004) produced transgenics expressing the HN protein of PPRV through *Agrobacterium*-mediated genetic transformation of cotyledonary node explants of pigeonpea. Kumar *et al.* (2004a) reported stable transformation of pigeonpea by using cotyledonary nodes from *in vitro*-grown seedlings of pigeonpea. Co-cultivation of the explants with strain C58 of *A. tumefaciens* harboring the binary plasmid pCambia1301 carrying *uidA* and *nptII* as reporter and selectable marker genes, respectively and rice chitinase gene as the candidate gene at late log phase with an O.D. of 0.6 and co-cultivation for 48 h resulted in stable transformation with 45% transformation efficiency. Pigeonpea transgenics resistant to *Spodoptera litura* were developed by Surekha *et al.* (2005) through direct regeneration of embryonal axis after infecting with the virulent strain GV2260 harboring a modified binary vector pPK202 carrying a synthetic *cryIE-C* gene under a constitutive 35S promoter and the marker gene neomycin phosphotransferase II (*nptII*). A co-cultivation period of 72 h was reported for transformation with *Agrobacterium* and obtained a transformation efficiency of 15%. More recently, Sharma *et al.* (2006a) reported the recovery of pigeonpea transgenics for insect resistance through direct organogenesis of axillary bud following 72 h co-cultivation with *A. tumefaciens* strain C58 harboring the binary plasmid pHS 723 having codon-optimized *cryIAb* and fused *nptII* and *uidA* genes.

2.3 Selection of the Transformed Tissues

A successful gene transfer does not guarantee stable integration and expression of the foreign gene, even by using signals for the regulation of

transgene expression. Antibiotic resistance genes allow the transformed cells expressing them to be selected from the populations of nontransformed cells. The population of cells that has been transformed and expresses a resistance gene is able to neutralize the toxic effect of the selective agent, either by detoxification of the antibiotic through enzymatic modification (Evans *et al.*, 1996; Joersbo *et al.*, 1998; Wang *et al.*, 2000; Jaiwal *et al.*, 2002) or by evasion of the antibiotic through alteration of the target (Jaiwal *et al.*, 2002). Effectiveness of a particular antibiotic resistance system depends mainly on elements such as, selective agent, explant used, and selectable marker genes. Amongst the most widely used antibiotic resistance genes as selectable markers, neomycin phosphotransferase II (*nptII*; Bevan *et al.*, 1983; Herrera-Estrella *et al.*, 1983) and hygromycin phosphotransferase (*hpt*; Van den Elzen *et al.*, 1985; Waldron *et al.*, 1985) are most common. Other selectable marker genes like gentamycin acetyltransferase (*accC3*) resistance, bleomycin and phleomycin resistance have also been employed, but are not used for routine transformations (Roa-Rodriguez and Nottenburg, 2003).

In pigeonpea so far only *nptII* and *hpt* genes have been employed for selecting the transgenic plants from untransformed ones. Concentration of the kanamycin used for selection of the transformants varied based on the explant used and mode of regeneration. For effective selection of transformants 50 mg l⁻¹ kanamycin in the medium was reported by Lawrence and Koundal (2001) and Satyavathi *et al.* (2003). Whereas, 75 and 125 mg l⁻¹ kanamycin concentrations were reported by Surekha *et al.* (2005) and Sharma *et al.* (2006a), respectively. Similarly, 5 mg l⁻¹ hygromycin as selection pressure for selecting the transgenics was reported by Kumar *et al.* (2004b).

2.4 Regeneration of Whole Plants

Recent advances in plant tissue culture techniques have been exploited *in vitro* regeneration of pigeonpea plants. Like any other crop, genetic engineering of pigeonpea requires reproducible tissue culture protocols. Though pigeonpea is a recalcitrant crop, ample reports on its regeneration through tissue culture are available (Kumar *et al.*,

1983, 1984; Shivaparakash *et al.*, 1994; Mohan and Krishnamurthy, 1998; Geetha *et al.*, 1999; Singh *et al.*, 2002; Dayal *et al.*, 2003; Thu *et al.*, 2003; Sharma *et al.*, 2006a). Regeneration in pigeonpea is by development of shoot buds by organogenesis from areas surrounding a meristem such as cotyledonary nodal meristem (Mehta and Mohan Ram, 1980; George and Eapen, 1994; Geetha *et al.*, 1998) and rarely through somatic embryogenesis (Patel *et al.*, 1994). However, only a few protocols could be successfully utilized in genetic transformation studies (Lawrence and Koundal, 2001; Satyavathi *et al.*, 2003; Kumar *et al.*, 2004b; Surekha *et al.*, 2005; Sharma *et al.*, 2006a, b).

Direct regeneration systems have advantages, due to the rapidity of morphogenesis and no requirement of frequent subculture. Besides, *de novo* production of shoot primordial is extremely rapid and initially synchronous with the period of cellular differentiation. Such a regeneration system favors easy accessibility for *Agrobacterium*-mediated genetic transformation in pigeonpea. Lawrence and Koundal (2001) reported indirect regeneration from callus obtained from the embryonal axes when cultured on MS medium fortified with 2 mg l⁻¹ BAP. This callus was used for infecting with *Agrobacterium* strain GV2260 containing the *CPTI* gene. For shoot initiation and development, the infected calluses were transferred to MS basal medium with 2 mg l⁻¹ BAP, 0.2 mg l⁻¹ IAA, and 50 mg l⁻¹ kanamycin. Rooting of the regenerated shoots was accomplished on half-strength MS medium containing 2% sucrose, 0.7% agar, and 0.5 mg l⁻¹ IBA (indole 3-butyric acid). However, this system resulted in a transformation efficiency of less than 1%.

Direct organogenesis from cotyledonary node and embryonic axes was obtained by culturing on MS media fortified with 8.87 µM BAP for initiation of shoot buds and 2.22 µM BAP for shoot elongation (Satyavathi *et al.*, 2003). And for rooting MS media supplemented with 1.48 µM IBA was used. Selection was applied after two days of co-cultivation with the *Agrobacterium* culture containing the *H*-gene. Using this method they obtained transformation frequency of 67% in cotyledonary node explants and 51% in embryonal axes, which was calculated as the number of explants survived the selection pressure. The same protocol was used by Prasad *et al.* (2004)

in producing pigeonpea transgenics expressing heamagglutinin- neuraminidase gene.

Kumar *et al.* (2004a) reported direct regeneration from cotyledonary nodal explants on MS medium supplemented with 2 mg l⁻¹ BAP. Further elongation of these shoots was obtained by culturing on MS medium supplemented with 0.5 mg l⁻¹ GA₃ (gibberellic acid) and rooted on root induction medium consisting of MS medium with 1 mg l⁻¹ IBA. Rooted plants were transferred to pots containing a 1:1 mixture of sand and soil and incubated for 1 week for acclimatization (by covering with a plastic bag initially and gradually exposing the plant to the open environment) prior to transfer to a glasshouse, thus obtaining a transformation frequency of 42.5%. Surekha *et al.* (2005) achieved regeneration from embryonal segments when cultured on MS medium fortified with 2 mg l⁻¹ BAP. The same medium was used for further development of shoots from embryonal axes after co-cultivation with *Agrobacterium* containing the *cryIE-C* gene. Elongation of the developed shoots was obtained by culturing on MS medium fortified with 1 mg l⁻¹ BAP, 3 mg l⁻¹ GA₃, and 0.1 mg l⁻¹ NAA (α-naphthaleneacetic acid). Elongated kanamycin (75 mg l⁻¹) resistant shoots were subsequently rooted on MS medium supplemented with 1.0 mg l⁻¹ NAA and later transferred to sterile vermiculite for hardening followed by transfer to the transgenic green house.

Recently, a highly efficient and genotype-independent direct organogenesis from the meristematic tissue developed from the axillary bud region of *in vitro*-grown seedlings of pigeonpea has been reported by Sharma *et al.* (2006a) by culturing the meristematic tissue on MS medium supplemented with 22.0 µM BAP for induction and development of shoot buds. Selection and enrichment of the transformed cells was initiated by applying a selection pressure of 125 mg l⁻¹ kanamycin in the media after 2 weeks of infection with *Agrobacterium*. For elongation developed shoots were transferred to Shoot elongation medium containing MS with 0.5 µM GA₃. Rooting of the elongated shoots were obtained by giving pulse treatment with 25 µM IAA and culturing on plane MS medium with 1% sucrose (Figure 1a–k). Using this method 60% transformation efficiency was obtained that was calculated based on the positive gene integration.

Figure 1 Regeneration of multiple shoots from leaf explants derived from *in vitro* germinated seedlings of pigeonpea, *Cajanus cajan* L. (a) Seeds showing germination on MS medium after 7 days of culture, (b) five-day-old leaf explants on MS medium supplemented with 5.0 μM BAP and 5.0 μM kinetin (shoot induction medium (SIM)) after carefully cutting and removing the preformed meristematic region, (c) swelling of the petiolar region after 5 days resulting in the induction of adventitious shoot buds, (d, e) leaf explant with half-cut lamina showing multiple shoot initiation and development on reduced SIM (MS+ 2.5 μM BA+ 2.5 μM kinetin), (f) multiple shoot formation after 21 days of culture from the petiolar cut end, (g) explant with elongated shoot in shoot elongation medium (SEM) containing MS supplemented with 0.58 μM GA₃, (h) elongated shoot after pulse treatment with IAA (11.2 μM) showing rooting on root induction medium (RIM), (i) well-developed plantlet just before its transfer to small pots, and (j, k) fully established healthy seedlings transferred into bigger pots (13 in.) containing sand:soil mixture.

2.5 Testing of Transgenic Plants

Selection and growth of plant cells on selective media provide initial phenotypic evidence for transformation. After selection, the putative transgenic shoot is propagated *in vitro* followed by rooting and transfer to the containment glasshouse for further evaluation and production of seeds from subsequent sexual generations. Molecular evidences are essential to further confirm the integration and expression of transferred genes followed by genetic characterization (Birch, 1997).

Transgenes are expected to behave as dominant genes due to their hemizygous state in recipient genome and thus segregate as dominant loci in a typical 3:1 Mendelian ratio (Campbell *et al.*, 2000). Successful genetic transformation of any plant involves not only the production of primary transformants showing stable expression of inserted gene but also the inheritance of introduced trait. Skewed segregation of the introduced genes, during meiosis leading to non-Mendelian inheritance may be caused due to various reasons, such as linkage to a recessive lethal gene, mutational effect of transfer DNA (T-DNA) insertion, and chromosomal rearrangement.

Satyavathi *et al.* (2003) were successful in producing oral vaccines in pigeonpea for rinderpest virus (RPV) disease in cattle by using surface glycoprotein *H*-gene of RPV. Presence and the expression of the candidate and marker genes were confirmed by polymerase chain reaction (PCR) analysis and reverse transcriptase-PCR (RT-PCR) analysis, respectively. Southern hybridization proved the integration of the genes with one to more than three copies of the gene. Expression at the protein level was confirmed by Western analysis and enzyme-linked immunosorbent assay (ELISA) for H-protein and was reported as 0.12–0.49% of the total soluble leaf protein in pigeonpea. Transgenic plants were analyzed till T₁ generation and observed 3:1 ratio of segregation of the genes. Oral vaccines were also produced in pigeonpea for another cattle disease, Peste des petits ruminants (PPR) by Prasad *et al.* (2004) using *HN* gene. Presence and integration of the transgene was confirmed by PCR and southern analysis and the protein expression through Western blot analysis.

Kumar *et al.* (2004b) produced pigeonpea transgenics with rice chitinase gene. The plants

were characterized by PCR and RT-PCR analysis for the confirmation of presence and expression of the gene. Plant DNA isolated was also subjected to southern hybridization for copy number and it varied from one to four. Plants were advanced to T₁ generation and the inheritance pattern followed Mendelian segregation.

Surekha *et al.* (2005) reported the molecular characterization of the produced pigeonpea transgenics using PCR and Southern blot analysis for *cryIE-C* gene. Protein analysis was carried out by Western blot analysis and the inheritance pattern followed Mendelian inheritance in T₁ and T₂ generations. Bioassays were performed using first and second instars of *S. litura* in T₁ and T₂ generations, which showed a varied response (60–80% mortality) for resistance to *Spodoptera*. Besides, Sharma *et al.* (2006a) produced pigeonpea transgenic plants resistant to *H. armigera* using *cryIAb* gene. PCR, Southern, and RT-PCR analysis were used for confirming the presence, integration, and expression at RNA level. Southern hybridization data had shown one to two copies of the integrated gene in the transgenic plants. All plant parts were used for ELISA analysis to check the expression of the *cryIAb* gene. The transgene protein level reported was as high as 0.1% in flowers and as low as 0.025% in leaves. The segregation of the genes were tested till T₃ generation and showed Mendelian inheritance (3:1). In all the available reports of pigeonpea transgenics (Table 2) there are no indication of adverse effects of genetic transformation methods on the growth, yield, and quality of the transgenic plants.

2.6 Regulatory Measures

In pigeonpea, no reports are so far available on commercially grown transgenics. At ICRISAT, transgenic pigeonpea plants carrying either the *cryIAb* (unpublished data) or the *cryIAc* (Sreelatha, 2006) genes were evaluated under contained field conditions with the approval of the Institutional Biosafety Committee (IBSC) of ICRISAT and the Department of Biotechnology, Government of India. However, these transgenic events are still under evaluation and validation.

Table 2 List of transgenic plants produced in pigeonpea

Explant	Mode of regeneration	Genes used	Mode of transformation	<i>Agrobacterium</i> strain used	References
Leaf disks	Direct organogenesis	<i>nptII</i> and <i>uidA</i>	<i>Agrobacterium</i>	LBA 4404	Arundhati, 1999
Shoot apices and cotyledonary node	Direct organogenesis	<i>nptII</i> and <i>uidA</i>	<i>Agrobacterium</i>	LBA 4404	Geetha <i>et al.</i> , 1999
Embryonic axes	Callus	<i>CPTI</i> , <i>nptII</i>	<i>Agrobacterium</i>	GV 2660	Lawrence and Koundal, 2001
Embryonic axes and cotyledonary node	Direct organogenesis	<i>H</i> -gene and <i>nptII</i>	<i>Agrobacterium</i>	EHA 105	Satyavathi <i>et al.</i> , 2003
Leaf	Direct organogenesis	<i>nptII</i> and <i>uidA</i>	Biolistics	–	Dayal <i>et al.</i> , 2003
Cotyledonary node	Direct organogenesis	<i>nptII</i> and <i>uidA</i>	Biolistics	–	Thu <i>et al.</i> , 2003
		<i>H-N</i> gene and <i>nptII</i>	<i>Agrobacterium</i>	GV3 101	Prasad <i>et al.</i> , 2004
		<i>hpt</i> and <i>uidA</i>	<i>Agrobacterium</i>	C58	Kumar <i>et al.</i> , 2004a
		<i>R chit</i> , <i>nptII</i> and <i>uidA</i>	<i>Agrobacterium</i>	C58	Kumar <i>et al.</i> , 2004b
Shot apices	Direct organogenesis	<i>hpt</i> and <i>uidA</i>	<i>Agrobacterium</i>	C58	Singh <i>et al.</i> , 2004
Embryo axis	Direct organogenesis	<i>cryIE-C</i> and <i>nptII</i>	<i>Agrobacterium</i>	GV 2260	Surekha <i>et al.</i> , 2005
Axillary meristem	Direct organogenesis	<i>cryIAb</i> and <i>nptII</i>	<i>Agrobacterium</i>	C58	Sharma <i>et al.</i> , 2006a

3. FUTURE ROAD MAP

3.1 Expected Products

The majority of protein food in India comes from pulses, grown invariably under unfavorable growing conditions that result in low productivity. Pigeonpea suffers from damage caused by biotic and abiotic stresses and due to these constraints it had a low compound growth rate of 0.8% in production between 1950 and 2004 (Ahlawat *et al.*, 2005). To combat the biotic stresses farmers rely on application of insecticides. Unfortunately, chemical control of insect pests is under increasing pressure due to environmental degradation, adverse effects on human health and other organisms, eradication of beneficial insects, and development of pesticide resistant insects. Improvement of pigeonpea through conventional breeding methods was slow though its wild varieties were rich source for insect resistance. Together with improved techniques for plant genetic analysis and engineering, concepts of exploiting transgenic

plants have gained increasing scientific and economic importance. Even transgenic technology application in improving this crop has started in recent past as it was said to be a recalcitrant crop. Quality of pigeonpea in terms of nutrition, resistance to biotic and abiotic stresses has to be further probed ahead. Modern biotechnological tools in combination with traditional technologies hold great promise for augmenting agricultural productivity in quantity as well as quality. Here under are some of the important traits that can be improved in pigeonpea as well as extended in producing functional recombinant proteins using transgenic technology.

3.1.1 Insect resistance

Insect pest menace is the major factor that destabilizes crop productivity in agricultural ecosystems. A survey conducted among plant breeders, pathologists, and entomologists shows that breeding for resistance to insect pests is at the top of their priority list for many important crops

(Ranjekar *et al.*, 2003). Insect pest management by chemicals has brought about a considerable protection to crop yields over the past five decades. The pod borer, *H. armigera* is commonly regarded as the key pest throughout Africa and Asia on pigeonpea. It is particularly damaging on early formed pods. In many parts of India the podfly, *M. obtuse*, takes over as the dominant pest later in the season. In pigeonpea, the losses due to *Helicoverpa* have been estimated at US\$ 317 million in the SAT, and possibly over US\$ 2 billion on different crops worldwide annually (Sharma *et al.*, 2001). Losses due to pod fly damage have been estimated to be US\$ 256 countries in Asia, Africa, and the Caribbean for food, million annually (ICRISAT, 1992). To overcome these losses, farmers resort to excessive use of pesticides. Crop surveys have indicated that before 1975, only 20% of the pigeonpea farmers were using insecticides, but by 1993, 100% of the farmers have adopted the use of chemicals to control *H. armigera* in India. In pigeonpea, one larva per plant reduces 4.95 green pods, 7.05 dry pods, 18.01 grains, 3.79 g pod weight and 2.05 g grain weight. Wild varieties are a precious source of resistance for insects attack in pigeonpea but genetic improvement of pigeonpea has been restricted due to the nonavailability of better genetic resources and strong sexual barriers with the wild species.

Insect resistant plant varieties, using δ -endotoxins of *Bacillus thuringiensis* (*Bt*), have been produced in several important crops such as tobacco, tomato, cotton, rice, brinjal, maize, broccoli, oilseed rape, soybean, walnut, poplar, sugarcane, apple, potato, groundnut, sweetpotato, chickpea, alfalfa, etc. (Hilder and Boulter, 1999; James, 2002; Sharma *et al.*, 2004). Of the US\$ 10 billion spent annually on insecticides worldwide, it has been estimated nearly US\$ 2.7 billion could be substituted with *Bt*-based biotechnology applications (Krattiger, 1997). There is significant increase in global area under transgenic crops from 1.7 million hectares in 1996 to 90 million hectares in 2005, in which *Bt* crops share was 25% of the total area (James, 2005).

Since the first report on the introduction of *Bt*-derived *cry* genes into tobacco (Barton *et al.*, 1987) and tomato (Fischhoff *et al.*, 1987; Vaeck *et al.*, 1987), there has been a rapid increase in the transformation of other crop plants to achieve resistance against insect pests and were successful (Stewart *et al.*, 1996; Nayak *et al.*, 1997; Adamczyk

et al., 2001a, b; Sanyal *et al.*, 2005). At least 10 different genes encoding different *Bt* toxins, namely, *cry1Aa*, *cry1Ab*, *cry1Ac*, *cry1Ba*, *cry1Ca*, *cry1H*, *cry2Aa*, *cry3A*, *cry6A*, and *cry9C* have been engineered into different crop plants (Schuler *et al.*, 1998). All these transgenics showed resistance to the respective pests. These results show that *Bt* gene is an efficient insecticidal gene that can be deployed for producing transgenic pigeonpea plants for pest resistance.

In pigeonpea, though transgenic plants with *Bt* and *CPTI* genes are available to combat the insect pest *H. armigera* more events with high expression need to be produced. Apart from *Bt* and protease inhibitor genes, insecticidal chitinase also been shown to be important in controlling the devastating pest, *Helicoverpa*, by dissolution of the chitin, an insoluble structural polysaccharide that occurs in the exoskeleton and gut lining of insects. Gene pyramiding with two different insecticidal genes and tissue-specific expression to reduce the risk of developing insect resistance are other attractive options to combat this pest and for durable resistance.

3.1.2 Fungal resistance

Fungal diseases involving 45 pathogens are known in pigeonpea and the most important and widespread disease is wilt (*F. udum*), favored by soil temperatures of 17–20 °C. It affects the plants at all stages of its development and in India it causes a loss of 5–20% and in severe case upto 50%. Recombinant-DNA technology allows the enhancement of inherent plant responses against a pathogen by either using single dominant resistance genes not normally present in the susceptible plant (Keen, 1999) or by choosing plant genes that intensify or trigger the expressions of existing defense mechanisms (Bent and Yu, 1999; Rommens and Kishmore, 2000). Transgenic pigeonpea for wilt resistance using rice chitinase gene has developed and are being evaluated for resistance against wilt at ICRISAT. But still much work has to be further done to develop transgenics with high expression of the gene.

3.1.3 Virus resistance

Viral diseases affect worldwide productivity of the economically important crops. In pigeonpea

the sterility mosaic disease considered as “green plague of pigeonpea” caused by sterility mosaic virus (SMD) is being recognized as a serious economic threat as it can cause complete crop failure if occurs early in the season. SMD infection at an early stage (<45 days old plants) results in a 95–100% loss in yield (Kannaiyan *et al.*, 1984; Reddy *et al.*, 1990), while losses from late infection (>45 days old plants) depend on the level of infection (i.e., number of affected branches per plant) and range from 26% to 97% (Kannaiyan *et al.*, 1984). Often the most significant weapons against viral diseases are cultural controls (such as removing diseased plants) and plant varieties bred to be resistant (or tolerant) to the virus, but they may not always be practical or available. There are mainly two approaches for developing genetically engineered resistance depending on the source of the genes used. The genes can be either from the pathogenic virus itself or from any other source. Substantial yield increase that was observed in field trials in some transgenic crop plants has clearly established the reliability of coat protein-mediated resistance (CPMR) as the most favored strategy to engineer resistance against many viruses. Apart from CPMR transgenics with replicase protein-mediated resistance is commonly produced for viral resistance and could be an option to develop pigeonpea transgenics with resistance to SMD.

3.1.4 Abiotic stresses

Drought, cold, heat, and salinity are the abiotic stresses that affect the pigeonpea yield. Besides, waterlogging, heavy rains and frost are very harmful for the crop. Hence, improvement of pigeonpea for tolerance to these abiotic stresses is very important as it increases the harvest index and ultimately the yield.

Though pigeonpea is classified as moderately sensitive to salinity (Keating and Fisher, 1985), development of salt-tolerant variety could be useful for Indian farmers as it is grown predominantly in the states of Uttar Pradesh, Gujarat, and Maharashtra, where more than 51% of the saline soils in India are located (Agarwal *et al.*, 1976). Moreover these states contribute about 85% of the total growing area and production of pigeonpea in India (Muller *et al.*, 1990). Also, pigeonpea is sensitive to photoperiod and temperature. Low temperatures

affect the short duration variety whereas high temperature and photoperiod affects the yield in medium and long-duration variety rendering them to terminal drought. In cool areas, maturity in long-duration pigeonpea is accelerated and severe competition occurs between intercropped maize whose maturity is delayed and pigeonpeas resulting in yield reduction of both crops.

Importance of transgenic technology in improving salinity tolerance has been already proved in *Arabidopsis* by overexpressing *SOS1* gene by limiting Na⁺ accumulation in plant cells (Shi *et al.*, 2003). The overexpression of a *AtNHX1* and *H⁺-PPiase* genes in *Arabidopsis* (Apse *et al.*, 1999; Gaxiola *et al.*, 2001) and *AtNHX1* gene in tomato and canola resulted in transgenic plants that were able to grow in high salt concentrations (Zhang and Blumwald, 2001; Zhang *et al.*, 2001). It is proven that membrane lipids hold the key for improvement of photosynthesis under low temperature and high temperature stress conditions (Grover *et al.*, 2000). Betaine has been shown to accumulate in response to low and high temperature stress in higher plants, where it might play a role in protecting membranes and/or protein complexes (Zhao *et al.*, 1992; Yang *et al.*, 1996). Introduction of choline dehydrogenase (*CDH*) gene that encodes betaine in tobacco resulted in low temperature tolerance a part from salt tolerance. Similarly, catalase in rice (Tanida and Saruyama, 1995; Tanida, 1996), *codA* gene in *Arabidopsis*, cDNA (complementary DNA) of chloroplast enzyme glycerol-3-phosphate acyltransferase in tobacco, and *Arabidopsis* have proven to impart resistance to various abiotic stresses including chilling and high temperatures. However, no transgenics are reported so far in pigeonpea for these traits. These results prove the feasibility of producing transgenics in pigeonpea for various abiotic stresses, which need to be improved for getting high yield varieties.

3.1.5 Biofortification

The efficiency of productivity depends on total nutrient content in the seed that meets the need of the population with minimal waste. Greater attention needs to be given to the pigeonpea to improve amino acids profiles, in particular to improve the level of sulfur-containing amino acids and to eliminate antinutritional factors.

Dissection of biosynthetic pathway and introducing appropriate genes or engineering entire biochemical pathway is generally applied for increasing the nutritional value of the crop. With similar strategies it should be possible to achieve similar increases in pigeonpea plants. Besides enhancing the nutritional value, transgenics produced for micronutrient deficiency such as Vitamin E can also produce antioxidants for industrial applications.

Biotechnology and genetic modification techniques are being optimized for the production and development of healthy foods, and improvement in the levels and activity of biologically active components in food plants (phytochemicals). The production of increased levels of β -carotene (provitamin A) in plants is especially important, as its precursor, lycopene has been shown to have physiological chemopreventive effects with regard to various cancers (Yan and Kerr, 2002). Furthermore, lycopene, commonly found in various carotenoids containing plants, such as tomatoes and carrots, is an essential ingredient in maintaining eye health and vision. β -carotene, α -carotene, β -cryptoxanthin are carotenes that are converted into Vitamin A or retinol in the body. Pigeonpea occupies an important place in human nutrition as a source of dietary proteins in several countries. Work has been initiated at ICRISAT in developing pigeonpea transgenics by using the phytoene synthase gene (*psy1*) that converts geranylgeranyl pyrophosphate to phytene. Increase in the phytene content during the biosynthetic pathway of carotenoids in turn increases the β -carotene level, which is a precursor of Vitamin A. Success in producing transgenic pigeonpea plants with high-level expression of phytene synthase will have much to contribute to the malnourished population. Besides, pigeonpea contains the lowest amount of limiting sulfur amino acids, methionine, and cysteine among all important food legumes, implicating the importance of these amino acids in its protein quality improvement program. The functional importance of dietary methionine and cysteine lies in the intestinal growth and function, beyond its role as a precursor for protein synthesis. Cysteine has a key role in cellular antioxidant function, which is a determinant of cell proliferation and survival. Promoting work in this direction could be helpful in increasing the protein quality of the pigeonpea. With this in view, production

of pigeonpea transgenics with *SSA* (sunflower seed albumin) gene that encodes methionine has been initiated at ICRISAT. Apart from this, considerable attention needs to be given to improve the quality of pigeonpea protein by reducing the polyphenolic compounds that are present in abundance that subsequently affects the activity of digestive enzymes.

3.1.6 Hybrid seed production

For hybrid seed production availability of cytoplasmic male sterile lines and restorer lines are necessary. The development of these lines through conventional breeding is a slow process that minimally requires several years of effort. In pigeonpea, using wide hybridization it was possible to produce CMS line and by screening large accessions, restorer lines were identified and were used to produce hybrids, which performed well in terms of biomass production and abiotic stress tolerance. But hybrid seed production was not to the expected level due to the high cost, poor in-built insect resistance, and management. Development of transgenics for CMS is possible as is the case in tobacco (Mouras *et al.*, 1999) where male sterility was induced by transferring the *u-atp9* (ATPase) gene. Also the development of transgenics by the introduction of transgenes in to the isogenic lines or in to the chloroplast of CMS line already available could reduce the risk of transgenes effect on pollinators such as honeybee and also could restrict the gene flow. Transgenic maintainer lines can be further utilized in enhancement of hybrid seed production with desired characters and also for development of inbred varieties.

Chloroplast engineering has been proposed as a safer approach to the containment of transgenes as chloroplasts are not transmitted in the pollen of flowering plants (Daniell and Khan, 2003; Ruiz and Daniell, 2005).

3.2 Addressing Risks and Concerns

The ethical dilemmas associated with the introducing of transgenic crops in the farming systems have divided both public and private researchers worldwide (Ortiz, 1998). This was not unexpected because the adoption of a new technology has

been always subject to distinct vision and ethical perspectives (Crouch and Ortiz, 2004). In times of severe global decline of biodiversity, proactive precaution is necessary and careful consideration of the likely expected effects of transgenic plants on biodiversity of plants and insects is mandatory (Wolfenbarger and Phifer, 2000; Velkov, 2001, 2003a, b).

Transgenic crops represent a powerful and profitable extension of conventional breeding methods in pigeonpea. However, challenge is to use this technology wisely, as part of a long-term strategy to improve human health, preserve biodiversity, and promote more sustainable agricultural practices in resource-poor countries. Enhancing the productivity of pulse legumes, such as pigeonpea, that are frugal in nature and are also important for nutritional security will be a possible way of addressing the additional problems of water deficits and high input costs in arid and SAT. Traditional cropping systems in pigeonpea include intercropping or mixed cropping (Aiyer, 1949; Acland, 1971; Osiru and Kibira, 1981) and crop rotation schemes for maintaining the soil fertility and minimizing erosion. Pigeonpea that is considered to be frugal in their requirement of water and fertilizers if made resistant to pests and pathogens using transgenic technology, could very well replace the cereals (maize, sorghum, pearl millet, and finger millet), fiber, and other legume crops allowing proper crop rotation and ensuring a diversification. Similarly, transgenic technology can contribute toward enhancing productivity and yield stability of pigeonpea with low-water requirement resulting in a dramatic reduction in the overall dependence on groundwater for irrigation.

However, a major concern of the scientists and the environmentalists is that the transgenes could escape to related species by pollen flow and could convert wild relatives into "super weeds." However, reports on pigeonpea indicate that "genetic pollution" by transgenes escaping into landraces, primitive cultivars, and nontransgenic varieties through pollen dispersal has been recently focused as a major issue in the risk assessment of transgenic plants. However, this risk can be very well addressed by introducing the transgenes into the chloroplast genomes of plants. These organelles are inherited maternally and therefore, pollen-based dispersal is not possible.

Breeding for resistance to pests and pathogens has been a major area of research in pigeonpea breeding. There is a concern that widespread growing of *Bt* transgenics may lead to insects developing resistance to *Bt* proteins, thereby increasing criticisms on the use of one of the most potent but more environmental-friendly pesticidal tool. Most of the pigeonpea transgenics produced so far using *cry1* genes that are insecticidal only to selected groups of insect species (e.g., lepidoptera) and are unlikely to have direct effects on species outside this group. Although the extensive testing on nontarget plant feeding insects and beneficial species that have accompanied the long term and wide scale use of *Bt* plants has not detected significant adverse effects (reviewed by O'Callaghan *et al.*, 2005). However, species representing pollinators (honeybees), natural enemies (including predators and parasitoids), and detritivores are among the insects that should be subjected to elaborate tests with transgenic pigeonpea containing insecticidal genes. However, there is an increasing concern that other transgenic proteins with ranges of activity wider than those of *Bt* may have a greater chance of affecting natural enemies. Transgenic expression of non-native proteins in plants may lead to the concerns on potential for new allergens in genetically modified (GM) crops substantiate the need for the complete risk assessment of transgenic crops before commercialization (Prescott *et al.*, 2005). Hence, an objective assessment of the associated hazards needs to be carried out during feeding trials for testing immunogenic responses of the transgenic foods on the animal model systems before any commercialization. Besides, concerns on the possibilities of breakdown of resistance to pests and pathogens is always there even if the resistance is based on the use of the secondary gene pool or through the use of the tertiary gene pool using conventional breeding methods. Although, this itself can be counteracted by imparting a more durable resistance in crop plants by diversifying the resistance-conferring genes, i.e., using more than one gene in a variety and eventually stacking genes, which confer resistance through diverse mechanisms.

The possible risks posed by cross hybridization with wild relatives have been extensively explored (reviewed in Stewart *et al.*, 2003). However, the Nuffield Council on Bioethics suggests that introgression of genetic material into related

species in centers of crop biodiversity is an insufficient justification to rule out the use of GM crops in the such areas and the developing world (Nuffiel Council on Bioethics (a discussion paper), 1999). Nonetheless, banning of transgenic crops does not appear as a scientifically sound option because of the potential benefits derived from their utilization by farmers, for example, resistant or tolerant crops to abiotic and biotic stresses obtained through genetic engineering (Sharma *et al.*, 2002).

The field evaluation and risk assessment have to be performed according to the biosafety guidelines of the host country under the immediate guidance and supervision of the Institute Biosafety Committee. Assessment procedures are being harmonized internationally by various organizations (Levin and Strauss, 1993). Hence, the release of transgenic materials should take place only after establishing the utility of the material through very transparent and well-documented evaluations. In addition to the measurable parameters such as the crop performance, yield, fitness, invasiveness, rate of hybridization, the expanded risk equation now also includes nonquantifiable terms such as consumer choice, long-term agricultural policy, ethics, and societal responsibility to future generations.

The key to the future of genetically engineered pigeonpeas is firstly the public awareness toward the competent assessed of any risk associated with the transgenics and also that the safety has been ensured. With the development of high-throughput technologies in sequencing, it is now possible to mine genes of high agronomic value from the near and distant relatives of crop plants and to introduce these gene(s) into recipient crop varieties through the techniques of genetic transformation. Understanding the mechanisms of resistance and the mining of alleles that will confer resistance to pests and pathogens will be the most rewarding area for development of resistant pigeonpea cultivars through transgenic approaches

3.3 Expected Technologies

3.3.1 Clean transgenics

The antibiotic resistance genes are often of importance to select for transformants from nontransformants in the process of producing

transgenic plants. But emergence of bacteria that are resistant to multiple or all antibiotics (Levy, 1997; Amtsblatt der Europäischen Gemeinschaften, 1998), transfer of resistance traits into weeds (Dale, 1992; Gressel, 1992) through cross-pollination with the related species and widespread distribution of resistance markers in to food products leading to horizontal transfer of resistance genes to gut bacteria, has increased the concern of antibiotic usage in transgenic plants. As these markers are used only as a tool of selection and as it does not code for any desirable traits the presence of these in transgenic plants is treated as a burden disturbing the genetic constituency of the plant and its wild varieties. Therefore, gene products need to be assessed for safety and environmental impact (Bryant and Leather, 1992; Gressel, 1992). Moreover, it is difficult to introduce a second gene of interest into a transgenic plant that already contains a resistance gene as a selectable marker because of limited availability of marker genes. The presence of multiple homologous sequences in plants enhances the likelihood for homology-dependent gene silencing (Matzke and Matzke, 1991), which could severely limit the reliable long-term use of transgenic crops. Therefore, it is necessary for scientists to look for alternatives for safer marker genes or elimination of the marker genes from transgenic plants to produce environmentally safe transgenic plants and pyramid a number of transgenes by repeated transformation (Yoder and Goldsbrough, 1994).

3.3.2 Marker-free transgenic plants

Marker-free transgenic plants can be obtained by using the site-specific recombinase P1 Cre/lox (Yoder and Goldsbrough, 1994; Vergunst and Hooykaas, 1998; Vergunst *et al.*, 1998; Gleave *et al.*, 1999) system. Marker gene to be introduced into the plant cell if placed between two lox sites will be excised from the plant genome by the expression of *Cre recombinase*. This technology was successful in producing marker-free transgenics in tobacco (Gleave *et al.*, 1999; Jia *et al.*, 2006). Besides cre/loxP, *Zygosaccharomyces rouxii* R/rs (Onouchi *et al.*, 1991; Sugita *et al.*, 1999, 2000) and *Saccharomyces cerevisiae* FLP/frt (Kilby *et al.*, 1995; Lyznik *et al.*, 1996; Davies

et al., 1999; Luo *et al.*, 2000; Gidoni *et al.*, 2001) recombination systems are also in use for producing the marker-free transgenics. Marker-free transgenic plants can also be obtained by using *ipt* gene attached to *Ac* transposable element as a marker. The transgenic plants acquires abnormal phenotype called extreme shooty phenotype and loses its ability to root and therefore can be differentiated visually from nontransgenic plants. As the marker is attached to an *Ac* transposable element during the transposition process the *ipt* gene may transpose or become lost along with the *Ac* element and thus a normal, marker-free transgenic plant can be obtained. Co-transformation of desired gene and the marker gene on separate plasmids within the same *Agrobacterium* strain and selecting the transformants with both the genes unlinked is another option for obtaining marker-free transgenics. The two T-DNA binary vector systems (Komari *et al.*, 1996; Xing *et al.*, 2000; Matthews *et al.*, 1997; McCormac *et al.*, 2001; Miller *et al.*, 2002) represent a useful approach to generate selectable marker-free transgenics by co-transformation of the vector harboring two T-DNAs each bearing a marker gene. This system represents a valuable approach to generate selectable marker-free plants, with a consistent frequency seen among three elite cultivars of rice decreasing the plasmid backbone transfer, lowering the number of T-DNA copy integrations, and avoiding artifacts due to gene silencing (Sharma *et al.*, 2005).

3.3.3 Alternatives to antibiotic resistance markers

It is not possible to remove marker genes once they are integrated into a plant genome unless a particular mechanism for removal is incorporated along with the marker gene and the gene of interest at the time of the transformation. The removal prior to commercialization of marker genes, which are driven by plant promoters and are used for selection of plant cells, has become the aim of both consumers and industry. Markers that confer resistance to chemicals other than antibiotics, such as herbicides, and lethal concentrations of the amino acids lysine and threonine and/or markers that enable the plant cells to grow in the presence of unusual nutrients, including cytokinin,

glucuronides, xylose or mannose, which will not allow nontransformed plant cells to grow can be the alternative selectable markers for plants. But expression of high levels of lysine and threonine causes abnormal growth in plant cells by interfering with amino acid biosynthesis and the presence of herbicide-tolerance markers may be undesirable. The relevant genes are therefore not suitable as marker systems.

Using a scorable marker gene could be an alternate for avoiding the usage of selectable antibiotic marker genes. The reporter genes or scorable markers produce a visible effect, directly or indirectly, due to their activity in the transformed cells. Scorable markers like *uidA* (*gus*) gene, and *cat* gene are commonly used in transformation experiments. However, destructive nature of β -glucuronidase (GUS) assay (Patnaik and Khurana, 2001) and presence of inhibitors of chloramphenicol-acetyltransferase (CAT) activity and endogenous CAT activity hampered the use of these as reporter genes (Patnaik and Khurana, 2001). Thus, to study the fate of introduced transgenes in living cells, vital reporter genes encoding for anthocyanin biosynthesis, green fluorescent protein, and firefly luciferase have been used successfully (Harvey *et al.*, 1999; Jordan, 2000). The delivery of a gene encoding mannose-6-phosphate isomerase and/or xylose isomerase allowing mannose and/or xylose to be metabolized in plant cells and the subsequent cultivation of those cells in a medium containing mannose and/or xylose as the sole source of sugar would allow only those cells that have taken up the gene to grow. Using mannose isomerase successful transformation of sugar beet (Joersbo *et al.*, 1998, 1999, 2000) and maize (Negrotto *et al.*, 2000; Wang *et al.*, 2000) was obtained. Using xylose isomerase, transgenics in potato, tomato, and tobacco were obtained with considerable transformation frequency (Haldrup *et al.*, 1998a, b). Another selectable marker gene that can be used is cyanamide hydratase (*Cah*) gene (Weeks, 2000). The *Cah* gene gives the transformed tissues the ability to grow on cyanamide-containing media by converting cyanamide into urea (which can be used as a fertilizer source).

Most alternatives are still in their development phase, are not widely available and will be difficult to implement in a less developed country. Alternative markers and marker removal systems

are being investigated in response to public concerns and to expand the number of tools available in plant molecular biology. Since the time for development of new alternative methods varies between different crops, it will be necessary to allow for a gradual transition to such technologies. It will also be critical to conduct safety assessments on new systems before they are used in products that are to be commercialized. Replacement of the technology, which makes use of antibiotic resistant marker gene such as *nptII*, will be desirable when the new technologies have ensured at least the same degree of scientific knowledge and confidence regarding their use as *nptII* gene and products containing it.

3.3.4 Choice of promoters

An efficient transformation system, in conjugation with the availability of a range of promoters with varied strengths and tissue specificities is critical to the success of transgenic approaches for crop improvement. An important aspect of transgenic technology is the regulated expression of the transgenes. Variation in transgene expression levels between different species and promoters may be due to different abundance of transcription factors, recognition of promoter sequences or intron splicing sites (Wilmink, 1995), or other factors. Therefore, increasingly, knowledge gained from genomics and postgenomics projects might provide information on designing of new targets for pigeonpea transformation. Establishment of transgenic systems for crops like pigeonpea requires genes of agronomic importance like those for insect resistance, abiotic stress tolerance, nutritional improvement, and male sterility. However, achieving a high expression of the introduced foreign gene in plant cells is still a challenging task. Direct screening of genomic libraries for highly expressed genes is an efficient way to identify promoters that confer high levels of gene expression. Tissue specificity of transgene expression is also an important consideration while deciding on the choice of the promoter, in order to increase the level of expression of the transgene. Thus, the strength of the promoter and the possibility of using stress inducible, developmental-stage- or tissue-specific promoters need to be considered (Bajaj *et al.*, 1999).

Besides, attention also needs to be focused on regulation of expression of plastid genes as well as to isolate target-specific promoters or design promoters with improved potential. Direct isolation of promoters can be done via T-DNA tagging with a promoterless reporter gene, although the most commonly used reporter gene for this kind of tagging has been the *gusA* gene (Casson *et al.*, 2002; Stangeland *et al.*, 2003), the ideal reporter gene should have a sensitive, nondestructive, and nontoxic assay allowing multiple *in vivo* screening rounds to identify simultaneously developmental specific, tissue specific, or stress-responsive patterns of expression.

The recent identification and isolation of a broad range of genes encoding different classes of proteins with activity against phytopathogenic fungi has opened the way to engineer fungus resistance into plants. Transgenic technology for imparting disease resistance requires tissue specific, wound- and pathogen-responsive promoters to express antifungal genes to control several diseases that threaten pigeonpea production. Similarly, for a number of future applications, transgenes will have to be expressed differentially or under specific abiotic (e.g., salt, wounding) stress conditions, which requires the use of a set of specific promoters to drive regulated gene expression. However, relatively few promoters are currently available for a specific or fine regulation of gene expression. It is expected that for these purposes homologous promoters will be more functional than heterologous ones, which should also raise less biosafety concerns.

3.3.5 Pyramiding of genes

Gene stacking is a term that is used in the context of genetically engineered crops, but is not a new idea in plant breeding. Gene stacking is combining desired traits into one line. Plant breeders are always stacking genes by making crosses between parents that each has a desired trait and then identifying offspring that have both of these desired traits. Pigeonpea breeders have been continually developing new varieties that contain the most effective combination of existing characters. A similar trend is expected with the pigeonpea transgenic plants by accumulation of

transgenes that inevitably becomes an increasing feature of new varieties. For example, stacking of different insecticidal genes might be considered as one of the major component of integrated pest management in pigeonpea. Bollgard[®] II developed by Monsanto that has been approved for commercialization in Australia and the United States in 2002 is an example for gene stacking, containing two *Bt* genes; *cry1Ac* and *cry2Ab2*. The proteins produced by these have different mode of action, thus making it very difficult for the pest to develop resistance to both the proteins simultaneously. Similarly, expected technological advancements in pigeonpea include identification and cloning of the genes responsible for traits such as high yield, disease resistance and tolerance to low temperature, to drought or to salt stresses. Although, this is a more difficult task because multiple genes control each trait for abiotic stress tolerance. However, in principle, the major genes involved in each of these traits can be identified first by mapping and then by map-based gene cloning (McCouch and Tanksley, 1991). This might ascertain that different varieties of transgenic pigeonpea plants endowed with a number of the above-mentioned desirable traits, will be grown in the dry and semi-arid regions of the world within the next 10 years.

3.4 Intellectual Property Rights (IPR) Issues

Intensive agriculture requires the use of certified seed (i.e., seed free of pathogens, pests, and weeds) and growers purchase new seed every year as an established practice. Historically, fertility and reproduction of grain and legume crops in Africa, Asia, and parts of the Americas have acquired a deep spiritual significance (Nuffiel Council on Bioethics, 1999). Nevertheless, the application of modern biotechnological techniques to plant species promises production of quality, quantity, and variety of food products. Hence, intellectual property rights are likely to play an important role in securing economic returns for the intellectual and financial investments that make the research and developments possible. The public-sector institutions need to obtain intellectual property rights for their discoveries so that these rights can be used in negotiations with the private sector to produce increased public benefit. Hence,

intellectual property regimes might facilitate the development of beneficial new crop varieties through individual, public, and corporate sources, as well as promote research collaboration.

Most pigeonpea growers prefer plant hybrid varieties that are more uniform and vigorous than ordinary varieties because of heterosis (hybrid vigor) and these advantages are lost when second generation seed is used. However, in many instances, small growers cannot afford to purchase new seed every year, and they wish to maintain their long-standing practice of saving some of the seed from one year's crop in order to plant next year's crop. Although pigeonpea is one of the major grain legume crops grown in the tropics and subtropics, none of the pigeonpea transgenics have been commercialized so far. Therefore, intellectual property rights need to be narrowly tailored to be commensurate with the actual scope of new GM inventions so as not to impede continuing research, innovation, and development of this important pulse legume. IPR issues in pigeonpea needs to be focused on making GM pigeonpeas available to developing countries by establishing a partnership between the research institutions and industries so that the benefits of research, applications, and licensing become much more widely available. Moreover, broad patents should be granted to companies that secure their competitiveness in the market place (<http://www.royalsoc.ac.uk/document.asp?id=1447>). Also, it is important to identify areas of common interest and opportunity between private sector and public-sector institutions so that the generation and use of pigeonpea transgenic not only to help resolve the intellectual property issues involved, but also benefit the poor.

4. CONCLUSIONS

Gene transfer techniques to develop transgenic crops can be seen as a logical extension of the crop plants for millennia displaying considerable potential to benefit both developed and developing countries. Genetic transformation is more expeditious, as the development of new cultivars by classical breeding typically takes from 10 to 15 years. Genetic transformation technology is critical in overcoming the severe bottlenecks associated with conventional

agricultural programs and enhancing their delivery prospects. However, transgenic technology needs to be used as adjunct to and not as substitutes for conventional technologies. Nevertheless, the primary attraction of the gene transfer methods to the plant breeder is the opportunity to tap into a wide gene pool to borrow traits, obviating the constraints of cross-compatible crop species. Most of the developments in plant gene transfer technology and the different strategies to produce improved transgenic plant varieties have been driven by the economic value of the species or the trait. These economic values, in turn, are mainly determined by their importance to agriculture in the developed world, particularly the United States and Western Europe. However, to increase global food production, it is necessary to ensure that this technology is effectively transferred to the developing world and adapted to local crops. The technological challenge here lies in obtaining improvements in agricultural productivity without destroying the global natural resource base. In the present scenario, many new approaches like gene tagging are being used to isolate resistance-conferring genes from resistant germplasm in crop species. Therefore, transgenic approaches can circumvent the difficulties of sterility and linkage drag, which do not allow the successful incorporation of resistance conferring genes from the wild species to crop species. Genetically engineered pigeonpea for virus resistance, insect resistance, and biofortification are good examples of strategies that could potentially benefit a diversity of legume crops. Substantial investments are therefore needed to develop, field test, and commercialize new transgenic pigeonpea varieties expressing insecticidal proteins, or proteins providing tolerance to herbicides or resistance to environmental stresses will revolutionize agriculture especially in arid and semi-arid regions of the world.

In addition, the scientific research aimed at risk analysis, prediction, and prevention, combined with adequate monitoring and stewardship, must continue so that negative ecological impact from GM crops will be kept to a minimum. One must also recognize the potential positive impact of GM crops on the environment, such as decreasing agricultural expansion to preserve wild ecosystems; improving air, soil, and water quality by promoting reduced tillage, reducing chemical

and fuel use; improving biodiversity through resuscitation of older varieties and promotion of beneficial insects; and cleaning up contaminated soil and air through phytoremediation. Since the implications of a risk assessment of GM organisms are dependent on the social context, a participatory approach is needed to determine the balance of benefits to risks. By understanding the nature of genetic modifications and the nature of genomic plasticity in plants, it would be possible to determine an accepted safety baseline, against which the safety of the genetic engineering of plants can be evaluated. To ensure safe crops to humans and the environment, a strong, but not stifling, regulatory system needs to be established and properly implemented. A challenge for the future will be to use this technology wisely, as part of a long-term strategy to improve human health, preserve biodiversity, and promote more sustainable agricultural practices.

Vetch

Rebecca Ford, Andi Munasifah Maddeppungeng and Paul W.J. Taylor

BioMarka, University of Melbourne, Parkville, Victoria, Australia

1. INTRODUCTION

1.1 History, Origin, and Distribution

Common vetch, *Vicia sativa* L., is an annual grain legume species and a member of the *Vicieae* tribe (Leguminosae-Papilionoideae) that originated from the arid regions of the Middle East. *Vicia* species have a broad geographical adaptation within Europe, Asia, North America, the temperate zones of South America, and tropical Africa, and more recently the Mediterranean soils and climates of southern Australia. *V. sativa* is a member of the *Vicia* subgenera, which comprises 50 species that are grouped into six sections (*Atossa*, *Hypechusa*, *Peregrinae*, *Vicia*, *Faba*, and *Pseudolathyrus*).

Vetch is traditionally grown as a mix for hay production or for grazing only on land unfavorable for other crop species that are more sensitive to adverse abiotic conditions. The species has considerable potential as a grain and forage legume (Seymour *et al.*, 2002). Vetch is also used as a disease break in rotations with other grain and green manure crops. The seeds contain between 28% and 32% protein and are considered to be a quality feed for ruminant animals, such as sheep and cattle. Vetch seeds have also been used for human consumption, particularly in times of food scarcity (Enneking, 1995). The world's five largest vetch producers are The Russian Federation, Spain, Ukraine, Turkey, and Ethiopia (FAO, 2005).

Common vetch can be grown on a wide range of soil types, from shallow duplex to heavy clays, and across a wide range of soil pH levels (4.5–9.0). Indeed, vetch is more suited to lower pH levels than many other cultivated legume species. However, vetch has poor tolerance to saline soils and soils those are prone to surface sealing, and is best suited to low to medium (<325–450 mm) rainfall areas (Seymour *et al.*, 2003). Vetch seedling development is hypogeal therefore, it is less likely to be killed by frost, wind erosion, or insect attack, as new stems can develop from buds at nodes at or below ground level (Seymour *et al.*, 2003).

V. sativa was introduced to Australia in the 1940s as an alternative leguminous rotation crop to field pea (*Pisum sativum*) due to its greater tolerance to adverse conditions as well as its immunity to pea weevil (*Bruchus pisorum*). Since 1990, the area sown has increased to over 230 000 ha/year primarily in southern Australia where it is grown for green manure, hay, or grazing. Australia ranks as the seventh largest world producer (FAO, 2004) and the majority of breeding efforts have focused on the *V. sativa* varieties Languedoc and Blanche fleur, which possess great potential for improvement in dry matter and seed yield (Seymour *et al.*, 2003).

The Blanche fleur *V. sativa* cultivar is a midmaturing vetch, which originated in France. The grain yields range from 0.5 to 3 tons per hectare. The distinguishing features of Blanche fleur are white flowers, which occur 95–125 days

after sowing as singles or pairs and orange colored cotyledons when the seed is split.

1.2 Neurotoxic Compounds in *V. sativa*

Several *V. sativa* accessions contain the neurotoxic compound β -cyanolalanine and its γ -glutamyl peptide (Ressler *et al.*, 1969). The natural occurrence of β -cyanolalanine was first detected and subsequently isolated and identified in *Vicia angustifolia* and *V. sativa* (Ressler, 1962). Seeds of the Blanche fleur cultivar contain approximately 1.15% of cyanolalanine toxins; i.e., 1.15 g for every 100 g of Blanche fleur seed (Panagiotopoulos, 2004).

The toxicity of these compounds to monogastric animals was demonstrated in several species. When administered to a weanling male rat by stomach tube in a dosage of 15 mg per 100 g, β -cyanolalanine caused hyperactivity, followed by tremors, convulsions, and rigidity, from which the rat recovered after 4 h. When a higher dose (20 mg per 100 g) was injected subcutaneously, it caused convulsions, rigidity, prostration, and death (Ressler, 1962). Poultry that were fed a diet containing 50% Blanche fleur seed had high mortality rates (Ressler *et al.*, 1969). More recently, the feeding of 5 kg per head of vetch hay to cows for a period of 2 weeks was shown to cause sudden death (Suter, 2002). The toxic compounds in vetch are also described as antifeeding factors (Tate, 1996). When consumed, the neurotoxic compound appears to trigger a defense mechanism that subsequently limits the animals food intake and in extreme cases, may result in the animal starving itself to death (Tate, 1996).

Due to the observed neurotoxic effects on monogastric animals, the β -cyanolalanine and γ -glutamyl- β -cyanolalanine compounds are thought to negatively affect humans, particularly in the brain tissue, although this has not yet been proven. Therefore, in order to be safely consumed by humans, vetch seed need to be boiled in water and the broth decanted during cooking. Lengthy steeping in water at room temperature will also effectively leach out the neurotoxins from split vetch seeds. However, these detoxification methods will also remove beneficial water-soluble

compounds such as B-vitamins, proteins, and carbohydrates (Ressler *et al.*, 1997).

1.3 Traditional Breeding and Limitations

Traditional breeding approaches have been applied with an aim to reduce and/or eliminate the neurotoxin compounds from elite Australian vetch accessions. To date, these methods have reduced seed toxin levels from 1.15% to between 0.3% and 0.4% of total seed protein. Two low toxins lines (IR-28 and IR-36) were identified from more than 3000 accessions from the International Center for Agricultural Research in Dry Areas (ICARDA), Iranian, and Russian germplasm collections. The low toxin lines were then crossed with commercial cultivated varieties. However, in order for vetch to be safely used as a fodder crop and moreover, for the seed to be consumed by humans and other monogastric animals, an amount of less than 0.1% of total protein or a zero toxin level is required. Novel and alternative breeding biotechnologies may offer a path toward the production of human-safe vetch. As an initial step toward this ultimate goal, several methodologies are required to be developed, such as reproducible and efficient transformation and regeneration systems, as well as a detailed understanding of the biochemical pathway(s) that produce the neurotoxin compounds. The neurotoxin β -cyanolalanine is synthesized as an intermediate in the assimilation of cyanide in plants by the catalytic enzyme β -cyanolalanine synthase (β -CAS). Another enzyme, γ -glutamyl transferase, functions to catalyze the formation of γ -glutamyl- β -cyanolalanine from β -cyanolalanine. The subsequent catalysis to asparagine is thought to be blocked in *V. sativa* (Fowden and Bell, 1965; Figure 1).

Considering the present knowledge regarding the neurotoxin biosyntheses, in terms of producing a neurotoxin-free plant, there are two possible strategies that can be applied to vetch. These are (1) to insert gene(s) that will activate β -cyanolalanine hydrolase activity, to lead to expression of asparagines, or (2) create a mechanism to suppress the activity of the enzymes that produce the neurotoxins, γ -glutamyl transferase, and/or β -CAS. Both of these strategies require the development of precise, robust, and reproducible

Figure 1 The biosynthetic pathway for β -cyanolalanine and γ -glutamyl- β -cyanolalanine

plant biotechnology techniques such as *in vitro* plant propagation and regeneration, and gene transformation.

2. DEVELOPMENT OF TRANSGENIC VETCH

The application of plant biotechnology to grain legumes has mainly been directed to isolation and characterization of genes that control useful agronomic traits that are qualitatively and quantitatively inherited. This has included genes for herbicide resistance, improved nutritional qualities, elimination of antinutritional factors, and improved features for cultivation and harvesting (Svetleva *et al.*, 2003). Although plant biotechnology offers numerous potential solutions to legume crops' improvement, to date, most studies on grain legume species are still at the stage of finding the best strategies for inserting foreign genes and the production of stable transgenic plants (Somers *et al.*, 2003). Therefore, a large amount of research is currently focused on the development of regeneration protocols from single cells and organized tissues, gene delivery methods, and the discovery of specific genes to be transferred to plant cells or tissues (Christou, 1997).

2.1 A Robust Regeneration System for *V. sativa* cv. Blanch fleur

Species belonging to the family *Leguminosae* are reported to be difficult to regenerate *in vitro* compared to nonlegume species mainly because legume regeneration *in vitro* is slow and is highly genotype specific (Somers *et al.*, 2003). Furthermore, members of the *Viciace* experience inhibition of explant growth in tissue culture from phenolic compounds (Bottinger *et al.*, 2001).

Legume regeneration *in vitro* has been achieved using two different processes, via organogenesis and somatic embryogenesis (Bottinger *et al.*, 2001). Both organogenesis and somatic embryogenesis techniques have been employed to produce regenerated plantlets either directly from an explant or indirectly after a callus phase (Svetleva *et al.*, 2003). Direct somatic embryogenesis occurs when cells undergo none or few mitotic divisions, whereas indirect somatic embryogenesis occurs following many mitotic divisions (Parrott *et al.*, 1995). Successful *in vitro* plant regeneration systems have been developed for legume species, such as peanut (Chengalrayan *et al.*, 2001) and soybean (Hofmann *et al.*, 2004).

In contrast, there has been limited success regarding the *in vitro* culture and/or regeneration of species from the *Viciace* tribe (Christou, 1997).

However, *in vitro* regeneration systems via somatic embryogenesis have previously been developed for recalcitrant related grain legume species and, based on these; two separate systems were recently developed for *V. sativa* (Maddeppungeng, 2006). One system was established from explants derived from etiolated seedlings, adapted from the methods employed for *Vicia narbonensis* (narbon bean; Pickardt *et al.*, 1989) and *Cicer arietinum* (chickpea; Kumar *et al.*, 1994). Another system was established from embryo axes explants and was adapted from the system developed for *Arachis hypogaea* seed (peanut; Baker *et al.*, 1995). Maddeppungeng (2006) determined that the most efficient method for somatic embryo callus production from cv. Blanch fleur was from epicotyl regions of etiolated seedlings (Figure 2a, b). This was far more efficient than using leaf explant material and was most successful when α -naphthaleneacetic acid (NAA) concentrations were higher than 8 μ M and the 6-benzylaminopurine (BAP) concentration was 13 μ M. Increased somatic embryo production was found in the presence of a low 2,4-D concentration (1 μ M). The compound 2,4-D was previously shown to affect somatic embryo production in the related species of narbon bean (Pickardt *et al.*, 1989) and chickpea (Barna and Wakhlu, 1993). The method of Maddeppungeng (2006) produced healthy and rooted regenerated *V. sativa* plantlets (Figure 2c) with a success rate of 12% achieved during the hardening off process.

2.2 A Robust Transformation System for *V. sativa* cv. Blanch fleur

Genetic transformation provides an attractive supplement to conventional breeding approaches

for legume species, particularly when the cultivated species contains extremely narrow genetic variation (Delannay *et al.*, 1983) and desirable genes are not present in the gene pool.

Various methods have previously been employed for delivering foreign genes, within genetic constructs, into the genomes of related legume and grain legume species. A direct gene transfer method was successfully applied to *Vigna aconitifolia* (moth bean). In this method, heat-shocked protoplasts were treated with polyethylene glycol (PEG) and plasmid DNA containing the coding region of the aminoglycoside phosphotransferase gene (*nptII*; Kohler *et al.*, 1987). However, the direct transformation system required protoplasts as the starting material and whole transgenic plants were not recovered (Kohler *et al.*, 1987; Sukhapinda *et al.*, 1987).

The particle gun bombardment or biolistic transformation method has successfully been applied to peanut (Deng *et al.*, 2001), soybean (Ponappa *et al.*, 1999), and *Lathyrus sativus* (Barna and Mehta, 1995). However, due to several drawbacks of this method, such as variable and often low transformation efficiency, variable insert copy numbers, patent issues, and high operation cost, the *Agrobacterium*-mediated transformation method has been more often employed for legumes. Several legume species successfully transformed with *Agrobacterium* include the model legume *Medicago truncatula* (Chabaud *et al.*, 2003), peanut (Sharma and Anjaiah, 2000), chickpea (Kar *et al.*, 1996), *Astragalus sinicus* (Chinese milk vetch; Cho and Widholm, 2002), soybean (Olhoft *et al.*, 2003), *Vigna sesquipedalis* Koern (asparagus bean; Ignacimuthu *et al.*, 1999), *Lupinus luteus* L (yellow lupin; Li *et al.*, 2000),

Figure 2 Regeneration of *V. sativa* cv. Blanche fleur via somatic embryogenesis from epicotyl-derived callus. (a) A heart-shaped embryo (magnification $\times 12$), (b) a regenerating plantlet, still attached to a callus clump, and (c) a fully formed plantlet with roots

Vigna mungo (blackgram; Saini *et al.*, 2003), lentil (Sarker *et al.*, 2003), narbon bean (Saalbach *et al.*, 1995), and faba bean (Bottinger *et al.*, 2001).

Recently, Maddeppungeng (2006) developed a transformation protocol for *V. sativa* cv. Blanch fleur using the *Agrobacterium*-mediated approach. For this, the selectable *NptII* gene marker, carried within a variation of the pLMNC95 binary vector (Mankin and Thompson, 2001) was applied and efficiently selected for at 50 mg l⁻¹ Kanamycin. The vector also carried a green fluorescent protein (GFP)-intron containing reporter gene for transformant observation. Experiments were conducted using the *Agrobacterium* strains EHA 101 (Hood *et al.*, 1986), LBA 4404 (Hoekema *et al.*, 1983), and C58 (Koncz and Schell, 1986) to infect epicotyl and leaf explants. Following 3 days of co-cultivation, explant pieces were placed on callus-formation media for up to 11 weeks after which putative regenerating transformant calli were observed microscopically with UV light and two different GFP filters (Figure 3). Since

the calli were resistant to kanamycin selection at 11 weeks after co-cultivation, this may have indicated stable transformation. However, further culture of calli into transgenic plants and Southern hybridization analysis to detect the transgene and copy number is required to confirm this.

Overall GFP expression was higher in epicotyl-derived callus than leaf-derived callus and the callus co-cultivated with the EHA 101 contained most GFP expression (Figure 3). Although GFP expression was observed in one of 22 regenerated putative transformant seedlings, this did not survive to maturity.

3. FUTURE ROAD MAP

3.1 Expected Technology Optimization

Although mature and fertile *V. sativa* cv. Blanche fleur plants have recently been established via somatic embryogenesis (Maddeppungeng, 2006),

Figure 3 GFP expression in *V. sativa* cv. Blanch fleur callus at 8 and 11 weeks after transformation

further research is required in order to make improvements for reducing the length of culturing time and increasing the regeneration efficiency. This may be achieved through the further investigation of the use of embryo axes as the explant source, a method previously shown to be genotype independent and highly successful in peanut (Baker *et al.*, 1995).

Further research is also required to optimize the stable integration of foreign genes through *Agrobacterium*-mediated transfer. Various tissues, organs, and cell types within a plant may differ in their susceptibility to *Agrobacterium* (Gelvin, 2000). The influence of starting material on transformation efficiency in the study of Maddeppungeng (2006) revealed that GFP expression was higher in epicotyl-originated calli (13.5%) than hypocotyl-originated calli (3.9%). The influence of starting material on the capability of transformant tissues to regenerate *in vitro* has also been observed for *Vigna radiata*. For *V. radiata*, 30–40% of leaf explants co-cultivated with *Agrobacterium*-developed kanamycin resistance and showed a positive expression of the β -glucuronidase (GUS) reporter gene, whereas 53% of hypocotyl explants developed kanamycin resistance and GUS positive calli (Jaiwal *et al.*, 2001). Furthermore, transformation frequency of *L. sativus* was strongly influenced by explant source. The number of transformed explants that expressed the GUS reporter gene was higher for leaf (10.6%) than stem nodal segments (12%) (Barna and Mehta, 1995).

The virulence of a particular *Agrobacterium* strain against a particular plant genotype or species is a key factor for the development of a successful and highly efficient transformation system (Nadolska-Orczyk and Orczyk, 2000). Often one strain is reported to be more efficient than other strains tested and several studies have been aimed at elucidating the efficacies of various *Agrobacterium* strains on transformation of different legume species. In an experiment on cotyledon explants of pea (*P. sativum*), the strain KYRT1 (4.66%) was found to be more efficient than AGL1 (1.59%) (Grant *et al.*, 2003). Whereas, strain EHA 105 was shown to be more virulent and better able to transform pea than the strains LBA4404 and C58 (Nadolska-Orczyk and Orczyk, 2000). Likewise, for the model legume *M. truncatula* cv. Jemalong, the efficiency of transformation using the AGL1 strain was higher

(96%) than using the strain LBA 4404 (56%) (Chabaud *et al.*, 2003).

The length of culture post inoculation may also have a significant influence on the level of GFP positive expression observed. In *A. sinicus* GFP transgenic expression studies, no cotyledon explants fluoresced until at least 4 weeks after transformation, at which point the characteristic green fluorescence was easily detectable in the explants transformed with the *Agrobacterium* strain EHA 105 containing pBINm-gfp5-ER (Cho and Widholm, 2002).

3.2 Expected Products

Once an optimized *in vitro* regeneration system as well as a transformation system for *V. sativa* cv. Blanch fleur has been established, research toward the development of neurotoxin-free genotypes through directed genetic manipulation may begin. However, the gene(s) of interest, to be inserted or down-regulated must first be chosen, dependant on which genes are functional in the biochemical and metabolic pathways responsible for neurotoxin production. These are genomic and functional studies that are yet to be performed. With current knowledge, there are three possible approaches to developing neurotoxin-free vetch using a genetic transformation approach: (1) silence the gene(s) that encode β -cyanoalanine synthase, (2) silence γ -glutamyl transferase, and (3) insert the gene that encodes β -cyanoalanine hydrolase, which appears to be absent. Indeed it may be possible to use the β -cyanoalanine synthase gene previously characterized by Pandian (2002) in a silencing cassette; however, more knowledge regarding the role(s) of this enzyme in *V. sativa* is first required. Particularly since high levels of cyanide accumulated in avocado after this gene was silenced (Yip and Yang, 1998), indicating its potential involvement in cyanide detoxification in *V. sativa*.

1. INTRODUCTION

Chickpea (*Cicer arietinum* L.), a self-pollinating diploid annual with $2n = 2x = 16$ chromosomes, is an important food legume crop throughout the world, especially in the developing countries. With over 10 million ha under cultivation in more than 30 countries in arid and semiarid areas of central, south, and southeast Asia, southern Europe, northern and eastern Africa, in the Americas and Australia, chickpea is second only to common bean (*Phaseolus vulgaris*) and third in production among the legumes. Chickpea is the only cultivated species belonging to the *Cicer* genus, which is a member of the Leguminosae family, Cicereae *Alef* tribe (van der Maesen, 1987). Commercially, the species is grouped into *desi* and *kabuli* types: *desi* chickpeas generally have small, colored seeds, whereas *kabulis* produce large, cream colored ones. *Kabulis* are usually utilized as whole grains while *desis* are decorticated and processed into flour. Chickpea is mainly used for human consumption and only a small proportion is used as feed. The chickpea seed is a good source of carbohydrates

and proteins, which together constitute 80% of the total dry seed weight. The crude protein content of chickpea varies from 17–24% containing the essential amino acids like tryptophan, methionine, and cysteine. Chickpea is a cool season annual crop performing optimally in 70–80 °F daytime temperatures and 64–70 °F night temperatures. The crop produces good yields in drier conditions because of the deep tap root system. During 2002–2004, the global chickpea production was 8.0 million tons from an area of 10.1 million ha, giving an average productivity of 786 kg ha⁻¹ (ICRISAT, 2007).

1.1 History, Origin, and Distribution

Chickpea with a moderately sized genome of around 750 Mbp (mega base pair) (Arumuganathan and Earle, 1991) evolved from its wild progenitor *Cicer reticulatum* through natural selection. Chickpea is one of the pulse crops domesticated in the Old World ca 7000 years ago (van der Maesen, 1987). Vavilov (1926) identified

two primary centers of origin, Southwest Asia and the Mediterranean, and one secondary center of origin, Ethiopia. Based on cytogenetical and seed protein analysis, Ladizinsky and Adler (1976) considered *C. reticulatum* as the wild progenitor of chickpea and southern Turkey as the center of origin for the crop. Three wild annual *Cicer* species, *C. bijugum*, *C. echinospermum*, and *C. reticulatum*, closely related to chickpea, co-habit with the cultivar in this area. In general morphology, physiology, and genetics, *C. reticulatum* comes closest to the cultigen, making it a possible contender as the progenitor of chickpea. However, taking into account the polymorphic nature of ancestral populations and complex nature of domestication, one cannot rule out other possibilities, such as *C. reticulatum* and the cultigen sharing a common ancestor or a polyphyletic origin of chickpea. The *Cicer* species occur from sea level (e.g., *C. arietinum*, *C. montbretii*) to over 5000 m (*C. microphyllum*) near glaciers in the Himalayas. Chickpea is the only domesticated species under the genus *Cicer*, which was originally classified in the tribe Viciae of the family Leguminosae and subfamily, Papilionoideae. Based on the pollen morphology and vascular anatomy, *Cicer* is now set aside from the members of Viciae and is classified in its own monogeneric tribe, Cicereae Alef.

1.2 Classification and Crossability

The genus *Cicer* comprises 43 species and is divided into two subgenera. Chromosome number in *Cicer* species can be generalized as $2n = 2x = 16$. The cultivated species, *C. arietinum* is found only in cultivation and cannot colonize successfully without human intervention. The wild species (e.g., *C. reticulatum*, *C. bijugum*) occur in weedy habitats, mountain slopes among rubble (e.g., *C. pungens*, *C. yamashitae*), and on forest soils, in broad-leaf or pine forests (e.g., *C. montbretii*, *C. floribundum*) and can be grouped into annual and perennial forms. Studies on biosystematic relations between chickpea and its wild relatives following interspecific hybridization have been limited to the nine annual species, *C. arietinum*, *C. reticulatum*, *C. echinospermum*, *C. judaicum*, *C. pinnatifidum*, *C. bijugum*, *C. cuneatum*, *C. chorassanicum*, and *C. yamashitae*.

Several groups have studied the genetic diversity and relatedness among annual *Cicer* species by employing hybridization, electrophoresis of seed storage proteins, isozymes, and molecular markers (Ladizinsky and Adler, 1976; van der Maesen, 1987; Kazan *et al.*, 1993; Labadi *et al.*, 1996; Sudupak *et al.*, 2002; Rajesh *et al.*, 2002; Nguyen *et al.*, 2004) leading to the classification of the wild species into three groups. The first group includes the primary and secondary crossability group, chickpea and its closest relatives (*C. reticulatum* and *C. echinospermum*); the second group (the annual tertiary group) consists of *C. pinnatifidum*, *C. judaicum*, and *C. bijugum*; while the third group includes mostly perennial tertiary species as well as two annual species *C. cuneatum* and *C. yamashitae*. Species within the primary gene pool (*C. arietinum*, *C. reticulatum*, and *C. echinospermum*) can be readily crossed usually generating fully fertile progeny; while species within the secondary gene pool (*C. bijugum*, *C. pinnatifidum*, and *C. judaicum*) can be successfully crossed with the cultigen *C. arietinum*, provided hybrid embryos are rescued. However, the progeny of crosses between primary and secondary gene pools are frequently sterile. Species within the tertiary gene pool (*C. cuneatum*, *C. yamashitae*, and others) have not yet been successfully crossed with the cultigen *C. arietinum*.

1.3 Consumers' Preference

During the past 20 years (1985–2004), the global chickpea area increased by 7%, yield by 24%, and production by 33%. Presently, the most important chickpea producing countries are India (64%), Turkey (8%), Pakistan (7%), Iran (3%), Mexico (3%), Myanmar (3%), Ethiopia (2%), Australia (2%), and Canada (1%) (ICRISAT, 2007). Although India produces a large variety of pulses, chickpea alone accounts for 43.2% of the total annual pulse production of 11.79 million tons. Chickpea has one of the highest nutritional compositions of any dry edible legumes and does not contain any specific major antinutritional factors. Chickpea seeds are eaten fresh as green vegetable, parched, fried, roasted, and boiled; as snack food, sweet, and condiments; seeds are ground and the flour can be used as soup, *dal*, and to make bread; prepared with pepper, salt, and lemon it is served as a side dish. *Dal* is the

split chickpea without its seed coat, dried and cooked into a thick soup or ground into flour for snacks and sweetmeats. Sprouted seeds are eaten as a vegetable or added to salads. Young plants and green pods are eaten like spinach. A small proportion of canned chickpea is also used in a few countries, and to produce fermented food. Animal feed is another use of chickpea in many developing countries. On an average, chickpea seed contains 23% protein, 64% total carbohydrates, 47% starch, 5% fat, 6% crude fiber, 6% soluble sugar, and 3% ash (ICRISAT, 2007). Chickpea protein digestibility is the highest among the dry edible legumes. The lipid fraction is high in unsaturated fatty acids, primarily linoleic and oleic acids. Chickpea is also known for its use in herbal medicine and cosmetics. Chickpea meets 80% of its nitrogen requirement from symbiotic nitrogen fixation and can fix up to 140 kg N ha^{-1} from atmosphere. It leaves substantial amount of residual nitrogen behind for subsequent crops and adds much needed organic matter to maintain and improve soil health, long-term fertility and sustainability of the ecosystems.

1.4 Productivity Constraints

Greater and more stable yields are the major goals of plant breeding programs. Chickpea yields are usually an average of $400\text{--}600 \text{ kg ha}^{-1}$, but can potentially surpass 2000 kg ha^{-1} , and in experiments have attained 5200 kg ha^{-1} . Yields from irrigated crops are 20–28% higher than those from rainfed crops. Despite considerable international investment in conventional breeding, productivity of the crop has not yet been significantly improved. Currently, productivity of chickpea is low (world average being $\sim 0.8 \text{ t ha}^{-1}$) (FAOSTAT, 2005) and has stagnated in recent years. Reasons underlying marginal improvements are series of biotic and abiotic stresses that reduce yield and yield stability. Especially *Ascochyta* blight and *Fusarium* wilt, pod borer, drought, and cold are the major constraints of yield improvement. The susceptibility of the plant to a foliar disease, *Ascochyta* blight, caused by the ascomycete *Ascochyta rabiei* and on the Indian subcontinent to the vascular disease *Fusarium* wilt, caused by *Fusarium oxysporum* f. sp. *ciceri* are the main constraints for increasing

yield. Consequently, chickpea breeding aims at high yielding cultivars that combine long-lasting resistance against *Fusarium* wilt and *Ascochyta* blight with tolerance to abiotic stresses, such as drought and cold. Many other factors also prevent increase in chickpea yield such as, inadequate amount of fertilizers and pesticides, and some of the traditional methods of land preparation and lack of knowledge of elite seed material. Improving resistance to biotic and tolerance to abiotic stresses as well as a general increase in dry matter are major aims of chickpea breeders around the world. Among the abiotic factors, drought stands to be the number one problem in major chickpea growing regions because the crop is grown on residual moisture and the crop is eventually exposed to terminal drought. In West Asia and North African countries, low temperature causing freezing injury or death or delayed onset of podding reduces yield tremendously. Heat and salinity problems are relatively important following drought and cold stresses. In general, estimates of yield losses by individual pests, diseases, or weeds range from 5–10% in temperate regions and 50–100% in tropical regions.

1.5 Rationale for Transgenic Chickpea Breeding

During the past 30 years, the area under cultivation of chickpea has remained stagnant but the production has increased from 6.3 metric tons (during 1975) to 7.4 metric tons (during 2002) because of increase in its productivity from 614 kg ha^{-1} to 735 kg ha^{-1} during this period (ICRISAT, 2007). It is generally accepted that the average yield of chickpea is below its presumed potential, and efforts to improve the productivity of this crop by conventional breeding means have not been very effective. The major reason behind this is lack of sufficient and satisfactory levels of genetic variability within the cultivated chickpea germplasm. Many wild annual *Cicer* species, which possess a wealth of agronomically desirable genes, are sexually incompatible with the cultivated varieties. An effective and alternative approach is, therefore, to transfer genes from sources which are otherwise difficult to introduce through conventional breeding (Meeting Report, 2000). Major yield increases could be achieved

by development and use of cultivars that tolerate/resist abiotic and biotic stresses. In recent years, the wide use of early maturing cultivars that escape drought stress led to significant increase in chickpea productivity. In the Mediterranean region, yield could be increased by shifting the sowing date from spring to winter. However, this is hampered by the sensitivity of the crop to low temperatures and the fungal pathogen *A. rabiei*. Drought, pod borer (*Helicoverpa* spp.) and the fungus *F. oxysporum* additionally reduce harvests there and in other parts of the world. Tolerance to rising salinity will be a future advantage in many regions. Therefore, chickpea breeding focuses on increasing yield by pyramiding genes for resistance/tolerance to the fungi, pod borer, salinity, cold, and drought into the elite germplasm. As chickpea is a self-pollinating crop with a narrow genetic base, there is not much scope for heterosis breeding in this crop. Pure line breeding was recognized as a method of choice for developing new chickpea varieties. Due to limited genetic variability available in this crop, there is not much hope for overall yield increase in chickpea.

Marker-assisted selection (MAS) is another approach for crop improvement where genes of specific agronomic interest are tagged with DNA markers and are transferred to the host plant through conventional breeding. In chickpea, genomic maps have been constructed, genes for resistance to fungi such as *F. oxysporum* and *Ascochyta* blight have been tagged and attempts are being made for MAS as reviewed by Ford and Taylor (2006). However, knowledge of the inheritance of agronomic characters is a basic requirement to identify and integrate interesting genes in linkage maps and to utilize these maps for MAS of these characters to accelerate the development of new cultivars. Nevertheless, most genomic regions harboring genes for important traits are not yet sufficiently saturated with co-dominant markers to apply MAS in chickpea breeding programs. Development of transgenic chickpea is, therefore, identified as an important approach for its improvement.

2. DEVELOPING TRANSGENIC CHICKPEA

Though chickpea is an important grain legume, it suffers from heavy losses due to susceptibility to

insect pests like pod borer, fungal pathogens, and low tolerance to drought and low temperature. As discussed earlier about the difficulty in developing new varieties that are superior to the available ones due to limitations in conventional breeding, it is imperative to develop superior varieties using transgenic technology. For development of transgenic plants, it is necessary to locate the genes those exhibit particular traits from available germplasm, their isolation, making them suitable to transfer into the target plant (modifying them by adding marker gene, promoter sequence, and termination sequence) and its transformation followed by an efficient regeneration protocol.

2.1 Locating and Isolating the Genes of Interest

Since there are significant losses in yield due to attack from viruses, fungi, and insects in chickpea, several attempts are being made to transfer specific coat protein genes and insecticidal protein genes from viruses and bacteria to produce virus resistant and insect resistant chickpea. It is very important to identify a set of germplasm of donor gene pools selected from individual crops for gene transfer studies and crop improvement. The contrasting growing regimes of cultivated chickpea and its wild progenitor may have resulted in a different allelic repertoire at different loci in the wild and cultivated gene pools. In recent years, attempts have been made to use wild *C. reticulatum* as a genetic resource for chickpea improvement (Abbo *et al.*, 2002). The world collection of chickpea germplasm contains genotypes that remain uncultivated because of poor agronomic characteristics, but possess a high level of resistance against *A. rabiei* that is a severe and destructive fungal disease (Collard *et al.*, 2001). Agronomic characters of wild *Cicer* species are presented in Table 1.

Development of gene-based markers to resolve the problems related to limited utilization of wild *Cicer* species by chickpea breeding programs can be used to provide candidate gene markers for mapping of quantitative trait loci (QTLs) controlling important agronomic traits. An expressed sequence tag (EST) library was constructed using root tissue from two very closely related chickpea genotypes. A total of 106 EST-based

markers were designed from 477 sequences with functional annotations and these were tested on *C. arietinum*. Forty-four EST markers were polymorphic when screened across nine *Cicer* species. Generated EST markers have detected high levels of polymorphism for both common and rare alleles. This suggests that they would be useful for allele mining of germplasm collections for identification of candidate accessions in the search for new sources of resistance to pests/diseases, and tolerance to abiotic stresses (Buhariwala *et al.*, 2005). Comparative biology and genomics are used to discover or validate the function of key genes. Resistance response to *Ascochyta* blight in four chickpea genotypes was studied using microarray technology and a set of chickpea unigenes, grasspea (*Lathyrus sativus* L.). ESTs and lentil (*Lens culinaris* Med.) resistance gene analogues. The four genotypes included resistant, moderately resistant, susceptible and wild relative of chickpea. The time course expression patterns of 756 microarray features resulted in the differential expression of 97 genes in at least one genotype at one time point (Coram and Pang, 2005, 2006).

Comparisons between genotypes resistant and susceptible to *A. rabiei* revealed potential gene “signatures” predictive of effective *A. rabiei* resistance. These genes included several pathogenesis-related proteins, SNAKIN2 antimicrobial peptide, proline-rich protein, disease resistance response protein DRRG49-C, environmental stress-inducible protein, leucine-zipper protein, polymorphic antigen membrane protein, Ca-binding protein, and several unknown proteins. The information generated enhances the understanding of this plant–pathogen relationship and may aid breeding programs directed toward the production of resistant cultivars (Coram and Pang, 2006). Bhattarai and Fettig (2005) reported that a wild relative of chickpea, *C. pinnatifidum*, is more tolerant than chickpea itself to various abiotic stresses, including drought. A complementary DNA (cDNA) clone encoding a dehydrin gene, *cpdhn1*, was isolated from a cDNA bank prepared from ripening seeds of *C. pinnatifidum*. The polypeptide deduced to correspond to this gene, *cpdhn1*, consists of 195 amino acid residues with a molecular mass of 20.4 kDa. Northern

blot analyses showed that *cpdhn1* expression was induced not only during seed development, but also in leaves in response to drought, chilling, and salinity and also to treatment with abscisic acid (ABA) or methyl jasmonate. The induction of *cpdhn1* expression by methyl jasmonate and ABA indicates that the gene may also be involved in the response to biotic stress. The CpDHN1 protein may thus improve the tolerance of chickpea to a variety of environmental stresses, both abiotic and biotic. In another work, Chen *et al.* (2004) identified three chickpea accessions, PI 559361, PI 559363, and W6 22589, showing a high level of resistance to *Didymella rabiei* (anamorph *Ascochyta*) pathotypes I and II, and can be utilized as resistance sources in chickpea breeding programs for resistance to *Ascochyta* blight. Previous studies on the genetics of chickpea resistance used undefined isolates of *D. rabiei*, and resulted in different genetic hypotheses involving one, two, or more resistance genes or QTLs (Hafiz and Ashraf, 1953; Singh and Reddy, 1983; Santra *et al.*, 2000; Tekeoglu *et al.*, 2000). Recent studies employing pathotype I or pathotype II isolates showed that resistance to pathotype I is conditioned by a single (major) gene, whereas resistance to pathotype II is conditioned by two or more independent loci (Udupa and Baum, 2003; Cho *et al.*, 2004). Another major factor limiting chickpea production is susceptibility to wilt disease (*F. oxysporum* f. sp. *ciceri*) that affects susceptible cultivars within 25 days after sowing and affected seedlings show drooping of leaves followed by complete collapse. Studies at ICRI SAT, Patancheru, India, revealed that at least three genes are involved in conferring resistance to *Fusarium* wilt, and earliness or lateness of wilting depends directly upon the number of genes contributing to the trait (Upadhyaya *et al.*, 1983).

2.2 Designing the Transgene for Effective Expression

Transgenic plant technology has become a flexible platform for cultivar improvement as well as for studying gene function in plants. As the process of transformation protocols was elucidated important information came to light that made the development of efficient plant transformation vectors possible. It is known that

the major determinant of gene expression (level, location, and timing) is the upstream of the coding region, which is termed as “the promoter”, and is of vital importance. Any genes that are to be expressed in the transformed plant have to possess a promoter that will function in plants. This is an important consideration as many of the genes that are to be expressed in plants, particularly reporter genes and selectable marker genes are of bacterial origin. They, therefore, have to be supplied with a promoter that will drive their expression in plants. Transgenes also need to have suitable “terminator” sequences at their 3' terminus to ensure that transcription ceases at the correct position. Failure to stop transcription can lead to the production of aberrant transcripts and can result in a range of deleterious effects, including inactivation of gene products, and increased gene silencing (Slater *et al.*, 2003b). Husnain *et al.* (1997) investigated the effects of different promoters, actin, cauliflower mosaic virus (CaMV), and Win6 on the expression of β -glucuronidase and kanamycin resistance marker genes introduced into zygotic embryos of chickpea. The CaMV promoter exhibited maximum efficiency at 44% followed by actin and Win6 promoters. Seed specific promoters are also useful for expression of foreign genes in the seeds. Shasany and Koundal (2000) isolated a *C. arietinum* legumin promoter, which shows similarity to chickpea 5' part of the legumin structural gene and strong homology with pea promoter and pea *legumin A* gene sequence. This promoter can be utilized for expression of foreign genes in seeds of chickpea. A chimaeric, truncated bacterial *cryIA(c)* gene construct was developed for plant expression with the CaMV 35S promoter, *nos* terminator, an initiatory kozak sequence, and a translational enhancer sequence of tobacco mosaic virus. This *cryIA(c)* gene was co-transferred with a plasmid-containing *nptII* gene as the selection marker. The *cryIA(c)* gene was inhibitory to the development of the feeding larvae of *Heliothis armigera* Hubner, the chickpea pod-borer (Kar *et al.*, 1997).

The efficient production of transgenic plants requires stringent selection procedures supported by a selectable marker gene that confers resistance to agents, such as antibiotics or herbicides. Several such selection systems have recently been described for grain legumes, based on the marker genes neomycin phosphotransferase

II (*nptII*), hygromycin phosphotransferase (*hph*, *aphIV* or *hyg*), phosphinothricin acetyltransferase (*bar* or *pat*), conferring resistance to kanamycin, hygromycin, and the herbicide phosphinotricin (BASTAM), respectively. Transformation of chickpea was done by a seed specific alpha amylase inhibitor (αAII) gene from *P. vulgaris* and the *nptII* gene as selectable marker (Sarmah *et al.*, 2004). At present, only a small number of reporter genes are in wide use in plant transformation vectors, these being β -glucuronidase (*uidA* or *gus*), green fluorescent protein (*gfp*), luciferase genes (*lux* and *luc*) and, to a lesser degree, the chloramphenicol acetyltransferase gene (*cat*) (Slater *et al.*, 2003c). Senthil *et al.* (2004) described the stable integration and the expression of marker genes through three generations of transformed chickpea plants. pGIN1 binary plasmid construct included an intron-containing *uidA* gene (coding for GUS) (Vancanneyt *et al.*, 1990) under the control of a CaMV 35S promoter and a CaMV 35S terminator along with a *bar* gene (bialaphos resistance) driven by a CaMV 35S promoter element with a nopaline synthase (*nos*)pA terminator sequence. Earlier reports (Fontana *et al.*, 1993; Kar *et al.*, 1996) did not provide substantial evidence for the stable integration of transgenes into the progeny of the primary transformants. Krishnamurthy *et al.* (2000) obtained a single sterile T₁ plant containing the *GUS* gene, which had no detectable expression of the marker gene. Tewari-Singh *et al.* (2004) described T₀ transformants using three different selection systems, and one of these transformants gave transgenic progeny. Polowick *et al.* (2004) constructed a plasmid contained a bi-functional fusion gene conferring both *gus* and *nptII* activities, under the control of a 35S35SAMV promoter for chickpea transformation. The plasmid contains a bi-functional fusion gene (*gus:nptII*) conferring both *gus* and *nptII* activities (Datla *et al.*, 1991) with a 35S35SAMV promoter (Datla *et al.*, 1993), a NOS (nopaline synthase) terminator, and an intron (Vancanneyt *et al.*, 1990). Sarmah *et al.* (2004) reported transformation of chickpeas with a seed-specific chimaeric gene encoding bean αAII , using *nptII* as the selectable marker gene. The selectable markers *bar* and *nptII* have both been used for production of transformed chickpeas (Molvig *et al.*, 1995; Kar *et al.*, 1996). But Sarmah *et al.* (2004) used *nptII* that confers resistance to kanamycin, has proved to be a reliable selection system.

Despite the improvements made in vector design and advances in our understanding of both the mechanisms of transgene integration and plant gene expression, plant transformation is still in many ways an imprecise art. If more than one gene are in the vector, different promoters and terminators should be used for each of them. The use of the same promoter and/or terminator can lead to an increase in gene silencing. Multiple genes in one vector should not be immediately adjacent to each other, and should be in the same orientation. This avoids adjacent inverted repeats that cause plasmid instability in bacteria and increased gene silencing in plants (Slater *et al.*, 2003d).

2.3 *In Vitro* Regeneration: A Prerequisite for Genetic Transformation

A reproducible, reliable transformation system, combined with traditional breeding techniques, could aid in improving both the quality and yield of a given crop (Polowick *et al.*, 2004). One of the prerequisites for successful gene transfer in plants is the availability of a suitable protocol for transformation, which is compatible with *in vitro* plant regeneration methods of the targeted species (Kar *et al.*, 1996). Two methods of plant regeneration are widely used in transformation studies, i.e., somatic embryogenesis and organogenesis. In somatic embryogenesis, embryolike structures (embryoids), which can be developed into whole plants in a way analogous to zygotic embryo, are formed from somatic tissues. These somatic embryos can be produced either directly or indirectly. On the other hand, organogenesis relies on the production of organs, either directly from an explant or from a callus culture by suitable manipulation of growth medium. Key to success in integrating plant tissue culture technology into plant transformation strategies is the realization that a quick and efficient regeneration system must be developed. However, this system must also allow high transformation efficiencies from whichever transformation technique is adopted (Slater *et al.*, 2003a).

In vitro plant regeneration in chickpea has been achieved from shoot meristem through organogenesis (Bajaj and Dhanju, 1979; Sharma *et al.*, 1979), immature cotyledons (Shri and Davis,

1992) and through embryogenesis from immature cotyledons (Sagare *et al.*, 1993). *In vitro* plant regeneration in chickpea has also been reported from leaflet callus (Barna and Wakhlu, 1993; Kumar *et al.*, 1994). Regeneration studies using various explants were reported to produce shoots, either indirectly through a callus phase (Khan and Ghosh, 1984; Barna and Wakhlu, 1994; Altinkut *et al.*, 1997) or directly (Shri and Davis, 1992; Kar *et al.*, 1996; Subhadra *et al.*, 1998; Chakrabarty *et al.*, 2000; Shikha *et al.*, 2001; Sarmah *et al.*, 2004). High numbers of shoots per explant were produced from surface sterilized half embryonic axes attached to a cotyledon (Sarmah *et al.*, 2004). An efficient protocol for the regeneration of whole chickpea plants using embryonic axes after removal of the shoot and root tips as well as the axillary bud has been shown by Jayanand *et al.* (2003). The concentration of growth regulator was first indicated as critical for growth and morphogenesis by Skoog and Miller (1957). They reported that a higher cytokinin to auxin ratio promotes shoot growth in contrast to Bajaj and Dhanju (1979), who reported that only cytokinin has significant effect on the induction of multiple shoot. Rao (1990) and Fontana *et al.* (1993) reported higher regeneration frequency in chickpea in presence of 6-benzylaminopurine (BAP). Kar *et al.* (1996) achieved multiple

shoot induction in chickpea using BAP and α -naphthaleneacetic acid (NAA) in regeneration medium. Thidiazuron in combination with BAP was also reported to produce multiple shoots in chickpea (Murthy *et al.*, 1996). Tissue culture and transformation conditions are strongly dependent on the genotype of explant (Adkins *et al.*, 1995). Genotype dependency of regeneration efficiency has been reported by Altinkut *et al.* (1997) using callus-derived plantlets and seedlings of chickpea. Reports on *in vitro* regeneration process of chickpea are presented in Table 2.

It is very important to identify a set of germplasm of donor gene pools selected from individual crops for gene transfer studies and crop improvement. The contrasting growing regimes of cultivated chickpea and its wild progenitor may have resulted in a different allelic repertoire at different loci in the wild and cultivated gene pools. In recent years, attempts have been made to use wild *C. reticulatum* as a genetic resource for chickpea improvement (Abbo *et al.*, 2002). The world collection of chickpea germplasm contains genotypes that remain uncultivated because of poor agronomic characteristics, but possess a strong capacity for resistance to *A. rabiei*. Wild relatives of *C. arietinum* also possess strong resistance, and may be bred with cultivated varieties to incorporate potential

resistance genes (Collard *et al.*, 2001). Targeted transfer of genes from the wild *Cicer* species into the cultivated species would represent an elegant application of transformation technology. Chickpea transformation, now considered as a routine procedure in chickpea improvement, has brought the application of this technology much closer to reality (Fontana *et al.*, 1993; Hamblin *et al.*, 1998; Chakrabarty *et al.*, 2000; Krishnamurthy *et al.*, 2000; Sharma and Ortiz, 2000; Jaiwal *et al.*, 2001). The applicability of this technology will, however, depend on the identification of key genes, the number of genes controlling a particular character, and public acceptance of cultivars resulting from transformation technology (Croser *et al.*, 2003).

2.4 Genetic Transformation

Two methods, namely *Agrobacterium*-mediated and particle bombardment, have extensively been employed for genetic transformation of crop plants. Regeneration via the callus lends itself easily (compared to explants regenerating directly) to *Agrobacterium*-mediated transformations, while direct regeneration is more amenable for particle bombardment (Chandra and Pental, 2003). *Agrobacterium*-mediated transformation has been used successfully in grain legumes for over a decade (Christou, 1997). Reports on genetic transformation of chickpea are presented in Table 3. Early transformation experiments, which relied on callus cultures, failed due to poor shoot regeneration but demonstrated the potential of *Agrobacterium tumefaciens* as a transformation vector for chickpea (Islam *et al.*, 1994). Fontana *et al.* (1993) first reported successful chickpea transformation. They used embryonic axes as explants, which were co-cultivated with *A. tumefaciens* and produced at least two independent plants, which were confirmed at molecular level. Subsequently, using almost similar experimental protocols, the formation of multiple shoots from different genotypes and the production of primary transgenic plants were reported (Kar *et al.*, 1996; Krishnamurthy *et al.*, 2000).

In the above-mentioned transformation protocols, the transgenic plants were selected via multiple cycle *in vitro* on media containing kanamycin (Fontana *et al.*, 1993; Kar *et al.*, 1996)

or phosphinothricin (Krishnamurthy *et al.*, 2000). Transformation frequencies and reproducibility in these early breakthroughs were low and limited their practical applicability. However, both transformation frequency and reproducibility have been improved recently in four separate studies (Polowick *et al.*, 2004; Sarmah *et al.*, 2004; Senthil *et al.*, 2004; Sanyal *et al.*, 2005), enabling the routine application of transformation technology to chickpea. In these protocols embryonic axes were used as explants. Cotyledonary explants containing half embryonic axes were used by Sarmah *et al.* (2004), while longitudinally sliced embryonic axes were used by Polowick *et al.* (2004) and Senthil *et al.* (2004). Sanyal *et al.* (2005) had precultured the explants (L2 layer) for 24 h on solidified MS-basal medium supplemented 1 mg l^{-1} BAP. The four systems appear equally useful and have some common elements like mature seeds are explant source, embryonic axes contain the target tissue, submersion of explants in *Agrobacterium* suspension followed by co-cultivation, frequent subcultures on selection medium, and transfer of rooted/grafted shoots to soil in the greenhouse. Although different groups have reported successful transformation of chickpea, the overall frequency of transformation is still very low (0.1–1.0%). Thus, to generate a sufficient number of transgenic lines with desired expression level a large number of explants need to be co-cultivated. In crops such as, maize and soybean, frequency of transformation has been dramatically enhanced with the use of Thiol compounds and L-cystine (Olhoft and Somers, 2001; Olhoft *et al.*, 2003). Similar efforts may also be made to improve the chickpea transformation efficiency. Use of super virulent strains of *A. tumefaciens* may be another option.

The biolistic gene (gene gun method) delivery where tungsten or gold particles are coated with the DNA that is to be used to transform the plant tissue has been successful in producing transgenic lines (Slater *et al.*, 2003e). There have been a few reports on production of transgenic chickpea plants using biolistic gene delivery. Kar *et al.* (1997) demonstrated the expression of *cryIA(c)* gene of *Bacillus thuringiensis* in transgenic chickpea plants. Explants and regeneration procedure were the same as their previous *Agrobacterium*-mediated transformation method, but only the gene construct and transformation

Table 3 Reports on genetic transformation of chickpea (*Cicer arietinum* L.) using various ex-plants, cultivars, methods of gene transfer, marker genes, and genes of interest

S. no.	Explant	Cultivar	Method of gene transfer	Genes transferred	Reference	Remark

method were different. Bio-Rad Biolistic 1000/He particle gun was used for delivering gene to the explants. Bacterial *cryIA(c)* gene was modified for plant expression. Transgenic kanamycin resistant chickpea plants were obtained through multiple shoot formation. Molecular analyses of the transformants indicated the presence of the transferred functional *cryIA(c)* gene in plant. The expression level of the *cryIA(c)* gene was

inhibitory to the development of the feeding larvae of *Heliothis armigera* Hubner, the chickpea pod borer.

Transient expression of marker genes in the zygotic embryos of chickpea was demonstrated and conditions for optimum transient expression of *gus* and *nptII* genes were established. When 12 µgm of plasmid DNA per milligram of tungsten particles accelerated with helium discharge at a

60 kg cm⁻² of mercury from a distance of 24 cm resulted in optimal transient expression of the *gus* and *nptII* gene in chickpea embryos (Husnain *et al.*, 1997).

2.5 Selection of Transformed Plants

The efficient production of transgenic plants requires stringent selection procedures supported by a selectable marker gene that confers resistance to agents such as antibiotics or herbicides. Several such selection systems have recently been described for grain legumes, based on the marker genes *nptII*, hygromycin phosphotransferase (*hph*, *aphIV*, or *hyg*), phosphinotricin acetyltransferase (*bar* or *pat*) conferring resistance to kanamycin, hygromycin, and the herbicide phosphinotricin (BASTAM), respectively (Chandra and Pental, 2003). In some cases, only a few transformed plants have been regenerated. Further optimizing the transformation parameters such as inoculation, co-culture condition, and selectable marker could increase transformation frequency. Although kanamycin has been the most favored selectable agent, it has not been proved an efficient selectable marker for grain legumes. The development of efficient uptake of selective agents by the regenerating tissues has increased recovery of transformed shoots, as has been shown by efficient selection in soybean on glufosinate-containing medium (Zhang *et al.*, 1999). The selectable markers *bar* and *nptII* have both been used for production of transformed chickpeas (Molvig *et al.*, 1995; Kar *et al.*, 1996). Sarmah *et al.* (2004) have used *nptII* in conjunction with kanamycin which has proved to be a reliable selection system where all of the plants selected based on kanamycin were proved to be transformed.

A rapid and reliable selection strategy has deterred chickpea improvement programs (Somers *et al.*, 2003). Tewari-Singh *et al.* (2004) developed an efficient and reliable nonantibiotic selection strategy using the *pat* and aspartate kinase (*AK*) genes for the production of transgenic chickpea. Kanamycin has been used for selection in most of the chickpea transformation studies reported (Fontana *et al.*, 1993; Kar *et al.*, 1996, 1997; Krishnamurthy *et al.*, 2000). There is only one report on the use of phosphinotricin (PPT) as a selective agent for chickpea (Krishnamurthy

et al., 2000), although it has been successfully used for selection in other legumes such as pea (Schroeder *et al.*, 1993, 1995; Bean *et al.*, 1997). Tewari-Singh *et al.* (2004) reported the use of the AK/LT selection system for the production of fertile transgenic chickpea. The results also showed that kanamycin and PPT can be used as selective agents for chickpea transformation. PPT was found to be a better selection marker than kanamycin as transgenic plants could be identified more easily and rapidly using the former.

3. FUTURE ROAD MAP FOR TRANSGENIC CHICKPEA

Although there has been an incremental increase in the productivity of chickpea during the past two decades using conventional breeding approaches, the productivity continues to be rather low, and far below the potential. The global chickpea demand in 2101 is estimated at 11.1 million metric tons, an increase of 29% from its level of 8.6 million metric tons during 2003–2004. Thus, a combination of productivity enhancement through genetic improvement might help achieving this target. Genes for transformation can be broadly divided into those that will be used to overcome the agronomic limitations (high yield potential, biotic and abiotic stresses) and the ones that could be used to enhance the value-added traits. Although major emphasis is currently being placed on improving the primary constraints, the manipulation of value-added traits, such as improving quality parameters like nutrition will be of much concern for chickpea improvement using transgenic technology. Transgenic technology could conceivably be used in chickpea for the introduction of disease–pest resistance; drought and salinity stress tolerance as well as value-added traits such as improved vitamins, micronutrients, and protein content thus enhancing the crop product value, quality, and safety. Current efforts include incorporating immunity or very high resistance to several viral and fungal diseases through transformation of chickpea cultivars that have very high demand for which no adapted resistant chickpea genotypes are available. Improved crop protection through the transfer and expression of disease resistance genes will decrease

or eliminate the usage of insecticides, pesticides, which are costly to the grower and may be harmful to the environment.

Finally, there are numerous traits that potentially could be manipulated with single or few gene introductions to produce more disease and pest resistant, drought and salinity tolerant, healthier, higher quality chickpeas.

3.1 Insect Resistance

The extent of crop losses by pod borer (*Helicoverpa armigera* Hubner) has been estimated to over US\$ 1 billion annually where in chickpea it is estimated at over US\$ 400 million in South Asia alone. Thus, improving chickpea resistance to this pest through genetic transformation is likely to contribute to sustainable crop protection and environmental conservation. For intractable pest problems such as *Helicoverpa*, the presumption is that no single tactic will suffice in itself to contain this pest. It has long been recognized that host plant resistance would be one of the most effective management options, but thus far, the levels of resistance in the available chickpea germplasm have been found to be very low. Genes encoding insecticidal proteins can be extensively used in generating chickpea transgenic plants for resistance to pod borer. Advancement in transgenic technology has made it possible to impart resistance to this devastating insect-pest of chickpea using different insecticidal genes from microorganisms, such as *Bt* crystal protein genes. Toxins genes from *Bt* deployed through transgenic plants are environmentally benign and incentive is to have improved resistance to this damaging pest while reducing reliance on synthetic pesticides. Transgenic chickpeas using *cry1Ab*, *cry1Ac*, and *SBTI* genes have already been developed at ICRISAT and are being subjected to insect bioassays and evaluated under contained field trials (K.K. Sharma, personal communication). Besides use of *Bt* genes, genes of plant origin like, lectins, diverse proteases, protease and amylase inhibitors also hold great promise in development of insect resistance in chickpea. Another possibility is to achieve an early and selective control of pod borer by targeting its specific physiology. Hence, insect chitinase-based strategy with different or multiple chitinase genes for the control of *H. armigera* is worth using for

pod borer resistance in chickpea. These can also be used as companion transgenes, which, when engineered into the plant together with a *Bt* gene, multiply the effect of *Bt* δ -endotoxin by weakening the peritrophic membrane surrounding the insect midgut, thus improving resistance to the legume pod borer.

3.2 Disease Resistance

Chickpeas are susceptible to a number of fungal diseases, which affect the growth and productivity of this crop. Diseases of economic importance include *Fusarium* wilt (*F. oxysporum* f. sp. *ciceris*), *Ascochyta* blight (*A. rabiei*), botrytis gray mold (*Botrytis cinerea*), collar rot (*Sclerotium rolfsii*), and dry root rot (*Rhizoctonia bataticola*) among others. In chickpea, varieties need to be developed having multiple resistance against *Fusarium* wilt, collar and root rots, *Ascochyta* blight, and botrytis gray mold to succeed in farmers' fields. The way is now open to the testing of genetic transformation approaches designed to enhance fungal resistance in chickpeas. Hydrolytic enzymes such as chitinases and glucanases, which degrade the fungal cell wall components, also pose as attractive candidates for development of disease resistant chickpeas. The endochitinase derived from the biocontrol fungus *Trichoderma harzianum* appears to be particularly effective in inducing resistance to fungi and this version of endochitinase can also be used for genetic transformation purposes. Besides, another set of antifungal genes encoding for polygalacturonase-inhibiting proteins (PGIP) (that inhibit one or more key enzymes used by *Botrytis* and some other pathogenic fungi during invasion, thereby delaying the disease long enough for other defenses to take over) may be explored for transformation purposes in chickpea. Resistance to fungal diseases in chickpea can be achieved by using another group of plant derived secondary compounds known as phytoalexins, which have a direct inhibitory effect on the growth of fungal pathogens.

3.3 Biofortification

Improvement in nutritional quality traits is important for providing better nutrition to the consumers. In developed countries, there is already

a growing interest in use of chickpea as functional food or nutraceuticals and in developing dietary supplements (P.M. Gaur, personal communication). Chickpea is deficient in the sulfur-containing essential amino acids methionine and cystine, which lower its dietary and nutritional value. The nutritional quality of chickpea can be improved by either raising the level of sulfur-containing amino acids of storage proteins or by changing the proportion of methionine-rich proteins already present in the seeds. High methionine trait cannot be produced by conventional breeding methods because of its failure to detect genotypes containing desirable levels of methionine. There are reports on transferring a gene encoding a methionine-rich seed 2S albumin from sunflower to lupins. The albumin constituted 5% of the total protein in the seeds of the transgenic lupins and led to the doubling of the seed protein methionine. This approach might as well prove to be an alternative approach for developing methionine-rich chickpeas.

Although chickpea already contains higher amounts of carotenoids such as β -carotene, cryptoxanthin, lutein, and zeaxanthin than genetically engineered “golden rice” (Abbo *et al.*, 2005), the recent success in chickpea transformation technology might enable further enhancement according to the RDA (recommended dietary allowances) recommendations. The potential of such approaches is still largely unrealized but should yield seeds with enhanced nutritional quality for the future.

3.4 Enhancing Quality Traits

Chickpea does not contain any specific major antinutritional factors, such as ODAP in grasspea, vicin in faba bean, and trypsin inhibitors in soybean. However, A PA2-homologous protein, isolated from chickpea (*C. arietinum*), has been shown to have lectinlike properties and has been implicated in allergic responses in chickpea-sensitive individuals. This indicates that a reduction or removal of PA2 using genetic transformation approaches or gene silencing could lead to significant improvements in chickpea seed quality for food uses. Another negative factor ascribed to chickpea consumption is more flatulence due to higher concentrations of raffinose

family oligosaccharides (RFOs) than any other dry legumes. Genetically manipulating the level of RFOs has been achieved by inhibiting the enzyme galactinol synthase, which catalyzes the first committed reaction in the pathway involving the synthesis of galactinol from UDP-Gal and myo-inositol. However, a better strategy involving the activation of α -galactosidase isolated from a thermophilic bacterium (*Thermotoga neapolitana*) for degradation of RFOs can be used considering the physiological importance of the RFOs during seed development and storage. Promoting the synthesis of a galactosyl cyclitol “ciceritol” in chickpea that is more slowly hydrolyzed by α -galactosidase than the RFOs could be another alternative for the reduction of RFOs thereby imparting protection during seed development and storage.

3.5 Abiotic Stress Resistance

Chickpea improvement for adaptation to abiotic stresses is crucial for stabilizing the yield in this major food legume crop. Genetic transformation provides prospects to enhance tolerance of chickpea to abiotic stresses including drought, salinity, and low temperature. Enhancing the production of chickpea under water deficits is vital as it is a rainfed crop. However, multigenic and quantitative nature of drought makes it difficult to breed for abiotic stress tolerance using conventional plant breeding. Knowledge of key genes involved in tolerance may allow genetic transformation of chickpea using such genes thus speeding up the breeding process. For example, efforts on enhancing the drought tolerance in chickpea are ongoing in ICRISAT, where transgenics carrying *P5CSF129A* gene encoding Δ^1 -pyrroline-5-carboxylate synthetase driven by CaMV 35S promoter are being developed for overproduction of an osmolyte proline, which is known to have a role in osmotic adjustment and cell protection under water deficits. In another effort, *DREB1A* cDNA from *Arabidopsis thaliana*, capable of transactivating DRE-dependent transcription in plant cells under the control of stress inducible *rd29* promoter was introduced into a popular chickpea cultivar for improving drought and salinity tolerance in this important pulse crop (K.K. Sharma, unpublished results).

3.6 Nutrient Responsive Genotypes

With a shrinking area of quality arable land for agriculture and its increasing allocation to staple cereal or high value crops, it is unlikely that in future chickpea will be grown on lands that are better endowed with nutrients than on which it is grown at present. Mineral nutrient deficiency will, therefore, continue to be a major and increasing constraint to chickpea production. Mineral nutrient deficiencies commonly observed in major chickpea producing areas are: nitrogen (N) (due to suboptimal nitrogen fixation), phosphorus (P), sulfur (S), iron (Fe), zinc (Zn), and boron (B). It seems, therefore, realistic to expect some recovery of losses in yield due to nutrient deficiency through genetic improvement for increased nutrient acquisition. Detailed information about genetic aspects of plant mineral nutrition should be derived to augment research strategy for developing nutrient use efficient genotypes in chickpeas. Outputs of transgenic research in other crops, in due course of time, could be extended for enhancement of nutrient uptake mechanisms and salinity tolerance in chickpea.

1. INTRODUCTION

1.1 History, Origin, and Distribution

The genus *Lupinus* comprises herbaceous annuals and shrubby perennials in two main geographical distributions. One of these, the largest with around 500 taxa, occurs in the Americas from Alaska to the Andean highlands of Peru, Brazil, Uruguay, and Argentina. As opposed to the New World taxa, the Old World group comprises only 11 species that occur within the Mediterranean basin and extend into East Africa. Among this group are six species with rough seeds and six smooth-seeded species. It is species from this latter group (*Lupinus angustifolius*, *Lupinus albus*, and *Lupinus luteus*) that have received the greatest attention from plant breeders seeking to develop suitable crop types. Of the rough-seeded species only *Lupinus cosentinii* has had any breeding effort although there is renewed interest in this group and preliminary breeding work has been initiated with collected material for a number of species (Buirchell and Cowling, 1998). *Lupinus mutabilis* has been used as a grain crop for human consumption in the Andean region since pre-Columbian times and this is the only species from the New World that has received attention from plant breeders.

1.2 Botanical Description

The taxonomy of the genus in the New World has not been well studied and considerable uncertainty remains as to their origin and evolution. The smooth-seeded Mediterranean species seem most likely to have originated in western Asia (Turkey and Syria) but today comprise three distinct monospecific groups (*L. angustifolius*, *L. albus*, and *Lupinus micranthus*) plus the *L. luteus*/*Lupinus hispanicus* complex (Gladstones, 1998). Lupins in general are not tolerant to heavy shading, occurring in open cleared habitats and especially as pioneer species on disturbed sites. A few selections are able to persist in slightly alkaline soils but most thrive on deep well-drained acid/neutral soils. In the New World taxa, the common chromosome number is $2n = 48$ (e.g., *L. mutabilis*) but variations from 36 to 96 have been noted. In the Old World rough-seeded species chromosome numbers vary from $2n = 32$ in *L. cosentinii* to $2n = 42$ in *Lupinus pilosus*. The smooth-seeded species have higher chromosome numbers, with $2n = 40$ in *L. angustifolius*, 50 in *L. albus*, and $2n = 52$ in the remaining species. A full taxonomic/botanical treatment of the Mediterranean lupin species can be found in Gladstones (1974, 1998). There have been frequent

attempts to generate interspecific hybrids with an aim to secure favorable traits in the improved species, but there appear to be a number of genetic barriers and there has been little success to date (Atkins *et al.*, 1998).

1.3 Economic Importance

Across the whole genus lupins generally contain high levels of quinolizidine alkaloids in both foliage and mature seeds (Wink *et al.*, 1995; Wink, 2003). The seeds particularly are “bitter” and unpalatable, as well as toxic to both monogastric and ruminant animals. As a consequence, lupins that have been used traditionally for human food in Latin America and Egypt, for example are debittered by washing. Breeding in *L. angustifolius*, *L. albus*, and *L. luteus* has led to the development of varieties with much lower levels of alkaloids and as a result greater palatability in stock feed formulations or for human consumption.

The most important crop lupin is *L. angustifolius* (“narrow-leaved lupin” or NLL, and in the United States known as “blue lupine”) and in Australia is the major “pulse” crop where as much as 1 million hectares has been planted with more than 90% of this area in Western Australia. The Western Australian Lupin breeding program was driven by the need for a grain legume crop to sustain cereal production through rotation in cropping systems. Because of the predominance of deep coarse-textured, sandy, acid soils in the wheat belt, narrow-leaved lupin is the best adapted pulse for this purpose, producing grain yields of a ton per hectare or more of high protein grain and contributing a significant rotational benefit to a succeeding wheat/barley crop. The benefit stems from residual N in the soil together with a beneficial disease break and other less well-defined positive impacts (on soil structure, K availability and nutrient cycling). In this environment the soils are low in available N and lupins nodulate profusely, typically deriving more than 90% of their N from the atmosphere. Typically the symbiosis is hydrogenase uptake negative (hup^- ; Layzell *et al.*, 1979) and there is growing evidence that the hydrogen gas produced by root systems nodulated with hup^- rhizobia leads to further rotational benefits as a consequence of effects on the soil biota (Dong *et al.*, 2003).

1.4 Traditional Breeding

The major breeding goal before and following the Second World War was to select “sweet” genotypes that had lower levels of alkaloids and as a consequence greater palatability to grazing animals and increased potential as grain for human consumption (von Sengbusch, 1942; Gladstones, 1970). Equally important was selection for nonshattering pods and permeable seeds, earlier flowering, and shorter periods for grain filling. These traits were selected and used to develop a most successful breeding program for *L. angustifolius* (NLL) in Western Australia beginning in the 1950s and continuing today (Cowling *et al.*, 1998). Both natural and induced mutations were exploited in achieving success. Additional breeding goals included selection for resistance to a range of fungal and viral pathogens, frost tolerance, yield potential especially under increasing stand density, and plant architecture. More recently the NLL breeding program has sought to improve grain quality and specifically protein content. Current commercial NLL cultivars contain in excess of 35% protein on a whole seed basis with a relatively low content of S-containing amino acids (especially methionine), typical of many pulse grains (Pettersson, 1998). *L. luteus* cultivars have significantly higher protein levels and greater concentrations of essential amino acids (cysteine, methionine, and lysine). Lupins are unusual among grains in that mature seeds contain essentially no starch. The major carbohydrate reserves are heavily developed secondary-thickened cell walls in the cotyledons. Together with the thick seed coats, that are typical of all lupins, this material contributes to the relatively high fiber content of the grain. Carbohydrates in the seed coats are structural polysaccharides (cellulose and hemicelluloses) and in the cell walls of the cotyledons nonstructural polysaccharides rich in galactose, arabinose, and uronic acids (Pettersson, 1998).

1.5 Limitations of Conventional Breeding and Rationale for Transgenic Breeding

A significant limitation to NLL yield potential in cereal-based rotations is inadequate and incomplete weed control particularly by annual ryegrass

(*Lolium* spp.) that displays a high level of resistance to grass-specific herbicides, especially the triazines. Effective weed control is critical in dry land farming where early exploitation of soil moisture by highly competitive weeds at seeding and later in the season during grain filling seriously impacts yield. Consequently using genetic modification to introduce resistance to nonselective herbicides like glyphosate (Roundup®) and glufosinate (Basta®, Liberty®) in NLL could provide an innovative and effective means to address this need.

Lupins, like many other legume species, are characterized by prolific flowering but high rates of floral abortion and abscission (Pigeaire *et al.*, 1992). A range of environmental factors influence flower abortion and as a consequence lupins show low and variable harvest index and unstable yield. While significant improvement to pod set has been achieved from newer breeding lines of narrow-leaved lupin, there is good evidence for a central role of plant hormones, especially cytokinins, in determining abortion and a transgenic approach has been suggested (Atkins and Pigeaire, 1993).

Similarly, levels of S-containing amino acids are relatively low in legume grain proteins and this is also the case for lupins (Pettersson, 1998). While there is some variation in the methionine levels in seeds among different lupin species the slight variation within a species does not encourage selection for this trait from the available germplasm. It has been proposed that transformation with genes encoding plant proteins richer in essential amino acids and particularly methionine would improve the amino acid composition of the seed and sunflower albumin has been introduced into *L. angustifolius* to address this (see below).

Lupins are prone to severe yield restriction as a consequence of both fungal and viral diseases (Sweetingham *et al.*, 1998). Conventional breeding has progressively introduced significant levels of resistance for some of the fungal pests (*Pleiochaeta* leaf spot and root rots, *Phomopsis*, *Sclerotinia*, and to some extent Anthracnose), for one of the major viruses, cucumber mosaic virus (CMV), but not at all for the major viral disease, bean yellow mosaic virus (BYMV). Transgenic approaches to provide resistance for BYMV in narrow-leaved lupin have been outlined (Atkins *et al.*, 1998).

2. DEVELOPMENT OF TRANSGENICS

2.1 Donor Genes

Genetic modification of lupins has used a number of different genes and constructs that are summarized in Table 1.

2.2 Transformation Methods Employed

All methods published for stable transformation of lupins use *Agrobacterium tumefaciens* as a vector. Stable transformation methods have been developed for *L. angustifolius* (Molvig *et al.*, 1997; Pigeaire *et al.*, 1997), *L. luteus* (Li *et al.*, 2000), and *L. mutabilis* (Babaoglu *et al.*, 2000). The explant used for inoculation in the method developed by Molvig *et al.* (1997) was slices of the embryonic axis isolated from immature seeds. Pigeaire *et al.* (1997) used the shoot apex of the embryonic axis of a mature seed as an explant for inoculation (Figure 1). The apex was wounded with a fine needle before introduction of *Agrobacterium* as this increased the infection significantly. Four different strains of *A. tumefaciens* were tested (LBA4404, EHA101, K61, AgL0) for infection and AgL0 was the most effective as judged by β -glucuronidase (GUS) staining in explants after 3 days of co-cultivation. Later experiments showed that AgL0 was more effective than AgL1 for transformation generating more transgenic shoots 6 months after inoculation (P.M.C. Smith, unpublished data). Many cultivars were also screened to determine their susceptibility to infection by *A. tumefaciens*. Of the 19 cultivars tested initially, Unicrop was most efficiently infected based on transient GUS assays on explants after co-cultivation (Pigeaire *et al.*, 1997). Li *et al.* (2000) used the method of Pigeaire *et al.* (1997) for transformation of *L. luteus*.

Babaoglu *et al.* (2000) developed a method for *A. tumefaciens*-mediated transformation of *L. mutabilis* using a wounded shoot apex as the explant. The initial cell layers of the apex were removed before co-cultivation with *A. tumefaciens* strain 1065.

In addition to these methods for stable transformation of lupin species, *Agrobacterium rhizogenes* has been used to develop transformed hairy roots in *L. mutabilis* (Babaoglu *et al.*, 2004) and *L. albus* (Udhe-Stone *et al.*, 2005). For

Table 1 Genes used in transformation of lupin species

Species transformed	Desired trait	Donor gene (promoter, terminator)	Donor gene source	Selectable marker (promoter, terminator)	Other components (promoter, terminator)
<i>L. angustifolius</i>	Herbicide resistance ^(a)	<i>bar</i> (CaMV ^(g) 35S, <i>ocs</i> ^(h))	<i>Streptomyces hygroscopicus</i>	As for donor gene	<i>Uida</i> [GUS] (CaMV 35S, <i>nos</i>)

Figure 1 Lupin transformation process using the shoot apex as an explant (Pigeaire *et al.*, 1992). (a) Preparation of explants from germinated seeds. (b) The shoot apex explant that is infected with *Agrobacterium tumefaciens*. (c) An explant after co-cultivation, selection, and regeneration of shoots. (d) A plate of explants with regenerated shoots before they are subcultured. (e) Shoots removed from original explants after the first round of selection. (f) Shoots after three rounds of micropropagation with selection. The shoot in the middle was the original chimeric shoot. Axillary shoots removed from it can be seen around it. Those with more transformed tissue grow well while others that lack transformed cells do not survive on selective media

L. mutabilis hypocotyl, epicotyl, and stem explants were inoculated (Babaoglu *et al.*, 2004) and for *L. albus* the base of the root of a germinating seedling was excised and the wound inoculated (Udhe-Stone *et al.*, 2005). Much higher concentrations of isoflavones were produced in the transformed roots of *L. mutabilis* than in nontransformed roots and these levels could be sustained over a long period of time (Babaoglu *et al.*, 2004). This makes them an ideal potential source for commercial production of isoflavones.

2.3 Selection of Transformed Tissue

The *bar* gene from *Streptomyces hygroscopicus*, which encodes phosphinothricin acetyl transferase, was used as a selectable marker for transformed tissue in combination with the herbicide glufosinate (Basta®) for selection in both *L. angustifolius* (Molvig *et al.*, 1997; Pigeaire *et al.*, 1997) methods and for *L. luteus* (Li *et al.*, 2000). The *nptII* gene has also been tested as a selectable marker gene for *L. angustifolius* but it was not as effective as the *bar* gene with transformation frequencies approximately one third lower (Molvig

et al., 2003). Pigeaire *et al.* (1997) and Li *et al.* (2000) used a drop of Basta® on the top of the explant (shoot apex) for the initial selection after co-cultivation rather than incorporating the herbicide in the media. This method improved the efficiency of selection as the apex was still attached to the embryo and well removed from the media. After regenerating shoots had been removed for subculturing the Basta® was incorporated in the micropropagation medium.

For *L. mutabilis* Babaoglu *et al.* (2000) found use of the *nptII* gene as a selectable marker gene with kanamycin selection to be effective.

2.4 Regeneration of Whole Plants

In the *L. angustifolius* transformation method developed by Molvig *et al.* (1997), regeneration was achieved via organogenesis. Clumps were divided to produce single shoots and these were subcultured until ready for treatment with indolebutyric acid (IBA, 1 mg l⁻¹) to produce roots. This method was cultivar specific with only cv. Warrah producing transgenic plants and the transformation frequency was low (0.01%).

In the method of Pigeaire *et al.* (1997) for transformation of *L. angustifolius*, transformants are regenerated from axillary buds that develop as shoots on the apical dome explant (Figure 1). Since the process does not involve a *de novo* regeneration step (the axillary buds exist at the time of explant preparation) chimeric shoots may be produced. To increase the chance of obtaining transgenic progeny from these chimeras micropropagation on selective media is used (Figure 1). Micropropagation involves removal of axillary buds that develop on the shoots to fresh media. If these buds arose from a transgenic sector they survive and usually have more transgenic tissue than the parent shoot (Figure 1). At least four rounds of micropropagation are routinely done before transfer of the shoots to the glasshouse. Even with this micropropagation step, the germ cells are not always transformed and so the transgene is not transferred to progeny. Transgenic progeny are recovered from approximately 30% of transformed T₀ shoots. While the original shoots had to be grafted onto a nontransgenic root stock, growth of shoots on IBA (3 mg l⁻¹) is now used to promote root growth before shoots are transferred to the glasshouse (Atkins *et al.*, 1998). This method is used routinely for transformation of a range of *L. angustifolius* cultivars. Unicrop is still the most efficiently transformed (6.2% transformation frequency) but many of the more advanced breeding lines have now been trialed with transformation frequencies ranging from 1.1% for cv. Quilnock to 3.3% for cv. Merrit. Recent experiments where L-cysteine was incorporated into co-cultivation media for *L. angustifolius* increased transformation efficiency significantly (170% of control for plants on 200 or 400 µg l⁻¹) (L. Hogson, S. Chapple, and P.M.C. Smith, unpublished data). This modification to the Pigeaire *et al.* (1997) method may make transformation of *L. albus* possible with a number of transgenic shoots generated (N. Fletcher and P.M.C. Smith, unpublished data). There are still difficulties in transferring shoots to the glasshouse as IBA induction of roots does not work and grafting is difficult but recent work to produce hairy roots in *L. albus* (Udhe-Stone *et al.*, 2005) and to successfully graft *L. albus* shoots (Lee, 2005) may solve this problem.

A regeneration process similar to that for *L. angustifolius* (Pigeaire *et al.*, 1997) was used for *L.*

luteus transformation (Li *et al.*, 2000). However, these lupins shoots did not micropropagate in the same manner so the original shoot was used for seed production. Roots developed on IBA media for only 10% of shoots and grafting was used in most cases to obtain seed in the glasshouse (Li *et al.*, 2000). Transformation efficiency was low, ranging from 0.09% for cv. Juno to 0.32% for cv. Wodjil.

For *L. mutabilis* regenerated buds developed at the periphery of the apical meristem explant and transgenic shoots developed from these. The shoots were derived from elongating epicotyls (Babaoglu *et al.*, 2000). All the transgenic plants described by Babaoglu *et al.* (2000) originate from the same explant and are likely to represent a single transformation event so it is not possible to gauge the effectiveness of the protocol.

2.5 Testing for Activity and Stability of Transgenes, Adverse Effects on Growth, Yield, and Quality

For *L. luteus* and *L. mutabilis*, there are no subsequent reports describing transgenic lines after the initial publications. Research involving transgenic *L. angustifolius* has been concentrated in three main areas; herbicide resistance, improved seed quality, and disease resistance (Hamblin *et al.*, 1998). Narrow-leaved lupins resistant to the herbicide Basta® (glufosinate or phosphinothricin) were produced by Pigeaire *et al.* (1997) through introduction of the *bar* gene. These lines were grown for five generations with stable expression of the transgene. They had significant resistance to the herbicide and in field trials their yields were equivalent to the parent cultivar, Merrit (Atkins and Smith, 2003). There was potential for their use to control weeds in the wheat-lupin rotations used in Western Australia, however, commercial development was blocked due to intellectual property restrictions associated with use of the *bar* gene.

The most detailed characterization of a transgenic lupin line has been for the high-methionine *L. angustifolius* line produced by Molvig *et al.* (1997). Lupin seeds are deficient in sulfur containing amino acids and this limits their use as a source of protein in animal feed. Molvig *et al.* (1997) introduced the sunflower seed albumin

(*SSA*) gene, encoding a rumen stable protein rich in methionine and cysteine, into *L. angustifolius* cv. Warrah to address this problem. The gene was expressed from a seed-specific pea vicilin promoter. The lines were grown for a number of generations with stable expression of the transgene. Seeds in the resulting transgenic plants had 94% more methionine but 12% less cysteine than seeds of nontransgenic plants with an overall 19% increase in the total seed sulfur content. It was suggested that the reduction in cysteine in the transgenic seed occurs as a result of reduced accumulation of one of the endogenous storage proteins that are high in cysteine. It appears that the seed's ability to import sulfur may limit the amount of sulfur that can be accumulated even when the sink strength for sulfur has been increased (by expressing *SSA*) (Tabe and Droux, 2002).

Feeding trials have been used to compare the nutritive value of *SSA* expressing transgenic seed to that of the parent cultivar in rats (Molvig *et al.*, 1997), sheep (White *et al.*, 2000), broiler chickens (Ravindran *et al.*, 2002), and fish (Glencross *et al.*, 2003). There were no adverse effects from using transgenic seed as feed for animals. The transgenic seed gave a significant increase in live weight gain when compared with the nontransgenic seed in rat and sheep trials (Molvig *et al.*, 1997; White *et al.*, 2000) and for sheep there was an 8% higher rate of wool growth. Use of transgenic lupins in feeds for broiler chickens reduced the requirement for supplemental methionine in bird diets (Ravindran *et al.*, 2002). There appeared to be little value in the use of high methionine lupins as feed for fish (Glencross *et al.*, 2003). These results highlight the different nutritional requirements of different animals.

Seed meal from high methionine lupins has also been tested as a vaccine to suppress experimental asthma in mice (Smart *et al.*, 2003). This was tested as *SSA* has been suggested as a potential allergen. Mice fed seed meal from the transgenic lupin were less likely to develop the symptoms of experimental asthma when challenged with *SSA* than those fed meal from nontransgenic lupins. These results support the theory that plant-based vaccines may be therapeutic for protection against allergic diseases.

The high methionine transgenic lines have also been used to estimate the potential for gene flow from transgenic *L. angustifolius* crops (Hamblin

et al., 2005). Within 1.5 m from the transgenic crop, outcrossing was estimated at 2.7×10^{-4} . No outcrossing was detected at distances greater than 2.25 m.

A number of different genes have been tested for their efficacy in improving resistance to fungal and viral diseases in lupins (S. Wylie, S. Barker, and P.M.C. Smith, unpublished data) (see Table 1). A peroxidase gene from *Stylosanthes humilis* significantly increased tolerance of the transgenic line to *Pleiocheata* root rot but the extent of the resistance was no greater than resistance found in a conventionally bred line (J. Thomas, S. Chapple, S. Barker, and P.M.C. Smith, unpublished data). The most promising results are for resistance to the BYMV; the most important viral disease of lupins worldwide. A nontranslatable inverted repeat of part of the RNA-dependent RNA polymerase (replicase) gene segment of BYMV has been expressed in narrow-leaved lupin. Three lines carrying this synthetic resistance gene have been identified, which are immune to infection (S. Wylie, unpublished data). These lines are still in the early stages of development and further testing will be required to confirm their resistance.

The isopentenyl pyrophosphate transferase (*ipt*) gene has been expressed in narrow-leaved lupin with a flower specific promoter (TP12) to increase cytokinin levels during pod set in an attempt to reduce pod abortion (C.A. Atkins, P.M.C. Smith, and N.E. Emery, unpublished data). The resulting transgenic plants have patterns of branching quite different from that of the parent cultivar. While in nontransgenic lupins branches develop only from the lowest few axillary buds and from three or four buds directly below the main stem inflorescence, in the *ipt* transgenic lines branches develop from all axillary buds. The implications of the modification on yield are currently being investigated.

3. FUTURE ROAD MAP

3.1 Expected Products

Development of transgenic lupin varieties in Australia has all but stopped in the last 3 years. There are lines available that, with further development, could be released commercially if the legal (intellectual and regulatory) and funding issues (see below) were solved. All these lines are

L. angustifolius and include lupins with Basta® resistance, improved methionine content of seeds, and BYMV resistance.

3.2 Expected Technologies

Freedom to operate issues caused by use of the *bar* gene as a selectable marker and its presence in lines to be commercialized forced some changes to the protocol for transformation of *L. angustifolius*. Groups working on transformation of lupins in Australia now use twin transfer DNA (T-DNA) constructs for transformations where the product may be commercialized. In this method the selectable marker and gene of interest are carried on two separate T-DNAs that may integrate into the plant genome at different positions. This means that after selection of transgenic shoots (T₀ generation) segregation of the marker gene away from the gene of interest can occur to allow marker-free transgenic plants to be recovered in the T₁ generation. In the experiments using this technology to date, approximately 25% of lines showed segregation of the gene of interest away from the *bar* gene (L. Molvig, S. Wylie, S. Barker, T.J. Higgins, and P.M.C. Smith, unpublished data). Use of twin T-DNAs increases the amount of work required to produce a transgenic line as about four times more explants need to be infected and subsequently processed. The screening to identify plants segregating in the T₁ generation is also more arduous. However, production of marker-free transgenic plants carrying only the gene of interest will reduce problems associated with use of third party intellectual property (IP), which may impede release of a commercial product. In addition any regulatory issues associated with release of herbicide-resistant plants will be overcome and the transgenic plants produced are more likely to be accepted by the public.

3.3 IP Rights, Public Perceptions, Industrial Perspectives, and Political and Economic Consequences

IP problems associated with use of the *bar* gene blocked release of Basta® resistant lupins in the 1990s and since that time work done in Australia has sought to ensure that there is freedom to

operate with any transgenic lupin variety used. To achieve this, researchers have attempted to reduce their reliance on third party IP in the constructs used for transformation. For example, regulatory sequences from subclover stunt virus have been tested and found effective in controlling transgene expression and the CaMV 35S promoter is no longer used for lines that may be released commercially.

In Australia where most of the work with genetically modified lupins has been done there is currently a moratorium on growth of genetically modified plants in all but two states and territories. It is not clear when this moratorium will be lifted. Although field trials can be conducted, the public distrust of transgenic plants along with the inability to release new lines has reduced funding for the work on genetically modified lupins and the programs that existed have now been scaled back to almost nothing.

Note added in proof. The moratorium on release of GM crops has now been lifted in two Australian states, Victoria and New South Wales.

1. INTRODUCTION

1.1 History, Origin, and Distribution

The genus *Medicago* comprises over 60 annual and perennial species. Alfalfa (*Medicago sativa* L. and *Medicago falcata* L.) is a perennial species that has a long history of cultivation around the world (Russelle, 2001). The center of origin for alfalfa is likely the Middle East and the steppes of Central Asia. The record of its use by humans dates back to the 10th millennium BC at Abu Hureyra in present day Syria. By the 1st century BC, it had spread to Greece and China and the Roman Columella planted alfalfa in southern Spain by 100 AD. Alfalfa spread to North and South America by the 1700s and to New Zealand and Australia by around 1800. The crop was so revered as an excellent source of nutrition for livestock that people carried alfalfa with them and established the crop on six out of the seven continents by the early 1800s.

1.2 Botanical Description

Alfalfa develops an extensive, well-branched root system that is capable of penetrating deep into the soil. Root growth rates of 1.8 m per year are typical in loose soils (Johnson *et al.*, 1996) and metabolically active alfalfa roots have been found

18 m or more below ground level (Kiesselbach *et al.*, 1929). This deep root system allows alfalfa plants to access water and nutrients that are not available to more shallowly rooted annual plants, enabling established alfalfa plants to produce adequate yields under less than optimal rainfall conditions. Alfalfa has a chromosome complement of $x = 8$ with both diploid ($2n = 2x = 16$) and tetraploid forms ($2n = 4x = 32$) (Quiros and Bauchan, 1988).

1.3 Economic Importance

Alfalfa is widely grown for animal feed throughout the world. Alfalfa is known as the “Queen of the Forages” because it contains a high amount of crude protein, digestible fiber, and is an excellent source of vitamins and minerals for animals. In the United States, alfalfa is the fourth most widely grown crop with over 8.9 million hectares of alfalfa harvested in 2005 (USDA-NASS, 2006). In 2005, the US alfalfa cultivation for dry hay was over 70 million metric tons with a total direct value of over \$7 billion. It is typically harvested for 4 years (an establishment year plus three subsequent years). Depending on location, alfalfa is harvested three or more times each year by cutting the stems near ground level. On average across the United States, alfalfa yields 7.6 Mg of dry matter (DM) per hectare each year although yields can

vary by location from 4.5 (North Dakota) to 15.5 (California) Mg ha⁻¹ (USDA-NASS, 2006). In 2005, the national harvest of alfalfa was over 68 million metric tons (USDA-NASS, 2006). The technology for cultivation, harvesting, and storing alfalfa is well established, machinery for harvesting alfalfa is widely available, and farmers are familiar with alfalfa production. There is a well-developed industry for alfalfa cultivar development, seed production, processing, and distribution.

The high biomass potential of alfalfa is based on underground, typically unobserved traits. Alfalfa roots engage in a symbiotic relationship with the soil bacterium *Sinorhizobium meliloti*. This partnership between the plant and bacterium results in the formation of a unique organ, the root nodule, in which the bacterium is localized. The bacteria in root nodules take up nitrogen gas (N₂) and “fix” it into ammonia. The ammonia is assimilated through the action of plant enzymes to form glutamine and glutamate. The nitrogen-containing amide group is subsequently transferred to aspartate and asparagine for transport throughout the plant. On average, alfalfa fixes approximately 152 kg N₂ ha⁻¹ on an annual basis as a result of biological nitrogen fixation, which eliminates the need for applied nitrogen fertilizers (Russelle and Birr, 2004). Although a significant proportion of the fixed nitrogen is removed by forage harvest, fixed nitrogen is also returned to the soil for use by subsequent crops. This attribute of increasing soil fertility has made alfalfa and other plants in the legume family crucial components of agricultural systems worldwide. Cultivation of alfalfa has also been shown to improve soil quality, increase organic matter, and promote water penetration into soil. In addition, alfalfa sprouts are consumed by humans and alfalfa juice is being used in health food products for its flavonoid compounds.

1.4 Traditional Breeding

Alfalfa, a perennial with perfect flowers is naturally cross-pollinated by bees, tolerates comparatively little inbreeding, and can be vegetatively propagated by stem cuttings. All cultivars are autotetraploids and the inheritance of economic traits is, therefore, quite complex. The introgression of *M. falcata* into *M. sativa* increased the genetic variation and the range of

adaptation of this crop to temperate climates of all continents (Rumbaugh *et al.*, 1988). Nine highly diverse, distinct germplasm sources were introduced into North America from different regions of the world (Barnes *et al.*, 1977). Since the 1920s, geneticists have employed recurrent phenotypic selection taking advantage of additive genetic variance to successfully improve alfalfa for resistance to diseases and insects, and extend geographic adaptability. However, more complex quantitatively inherited traits, such as forage yield, have essentially not changed for the past 60 years (Brummer, 1999; Lamb *et al.*, 2006).

1.5 Limitations of Conventional Breeding and Rationale for Transgenic Breeding

Comprehensive genomic analysis of alfalfa is limited due to the large size of the genome and obligate outcrossing autotetraploid nature of alfalfa. Thus, varieties are synthetic populations, consisting of a heterogeneous mixture of heterozygous genotypes. Although improved varieties of alfalfa have been developed, little is known about the genes controlling desirable traits due to the plant's complex genetic system. The traits needed to improve alfalfa are complex and require a multifaceted approach to first understand the molecular underpinnings of the characteristic and subsequently to select or engineer improved plants. To increase the crop value and utility of alfalfa a number of characteristics need to be enhanced. In areas of severe winters, winter hardiness needs to be improved to extend stand life and retain high yields over multiple years. In areas with low rainfall, water use efficiency and tolerance to salinity need to be increased. In acid soils, tolerance to aluminum is needed as well as increased tolerance to waterlogged soils. Improving forage fiber digestibility would enhance nutritional quality for ruminant animals and decrease processing costs when using alfalfa fiber as a feedstock for bioethanol production.

The basic tools required for modern genome analysis are largely not available in alfalfa. Direct study of alfalfa in isolation is unlikely to yield rapid improvements for these characteristics. The use of an annual relative of alfalfa, *Medicago truncatula*, is an ideal candidate for parallel analysis of agronomically important genes in alfalfa.

2. DEVELOPMENT OF TRANSGENIC ALFALFA

2.1 Promoters for Transgenic Alfalfa

The cauliflower mosaic virus 35S (CaMV 35S) promoter is the most widely used promoter in alfalfa transgenic work. In an attempt to find alternative constitutive promoters for transgenic alfalfa, several authors evaluated many promoters for their efficacy driving the reporter gene β -glucuronidase (*gusA*) or green fluorescent protein (GFP). In one such work, Winicov *et al.* (2004) generated transgenic alfalfa that contained the MsPRP2 (proline rich protein 2) gene promoter from alfalfa driving GFP and NOS 3' transcription terminator. Transformation of alfalfa was accomplished by co-cultivation of alfalfa leaf discs with *Agrobacterium tumefaciens*. Kanamycin resistance conferred by a constitutive neomycin phosphotransferase (*nptII*) gene was used as a selectable marker. The MsPRP2 promoter showed root-specific reporter gene expression in transgenic alfalfa plants (Winicov *et al.*, 2004).

Samac *et al.* (2004b) generated transgenic alfalfa that contained the CaMV 35S promoter, the cassava vein mosaic virus (CsVMV) promoter, or the sugarcane bacilliform badnavirus (ScBV) promoter. Each promoter was fused separately to the reporter *gusA* gene and NOS 3' transcription terminator. Transformation of alfalfa was done by co-cultivation of leaf discs with *A. tumefaciens* strain LBA 4404. Kanamycin resistance conferred by the *nptII* gene was used as a selectable marker. The highest enzyme activity as well as *in situ* staining for β -glucuronidase (GUS) was obtained in transgenic alfalfa plants that contained the CsVMV promoter. In transgenic alfalfa leaves, GUS activity was observed in the order of CsVMV promoter > CaMV 35S promoter > ScBV promoter. The CsVMV promoter was expressed in all tissues examined. The 35S promoter was expressed in leaves, roots, and stems at moderate levels, but the promoter was not active in stem pith cells, root cortical cells, or in the symbiotic zones of nodules. The ScBV promoter was active primarily in vascular tissues throughout transgenic alfalfa plants studied.

The potato protease inhibitor II (PinII) promoter fused to the *gusA* gene and NOS 3' transcription terminator was introduced into alfalfa

by *Agrobacterium*-mediated transformation of leaf discs (Samac and Smigocki, 2003). Transformant alfalfa was selected by kanamycin resistance conferred by the *nptII* gene. Constitutive GUS expression was observed in leaf and root vascular tissues of transgenic alfalfa. In some transgenic alfalfa plants, GUS expression was observed in leaf mesophyll cells. Approximately twofold more GUS expression was observed following mechanical wounding of leaves compared to unwounded control alfalfa leaves (Samac and Smigocki, 2003).

2.2 Alfalfa Forage Quality Improvement

2.2.1 Manipulation of lignin and plant cell wall composition for forage quality improvement

Lignin is a polymer of monolignols that is found in secondarily thickened plant cell walls and is critical for structural integrity of the wall and the strength of stems. Alfalfa contains two major monolignols, monomethoxylated guaiacyl (G) and dimethoxylated syringyl (S) units. Increased lignin content and S/G ratio resulting from stem maturity have been linked with reduced forage digestibility by grazing animals and hence represent poor forage quality variables. Over the years, considerable effort has been made toward improving forage quality by suppressing the expression of plant genes that are thought to play a role in lignin content or modifying lignin composition in alfalfa. Improving forage digestibility provides a means to enhance animal production.

A cytochrome P450 gene from *M. truncatula* in antisense orientation, driven by the vascular-specific bean phenylalanine ammonia lyase (PAL2) promoter and NOS 3' transcription terminator was used to generate transgenic alfalfa (Reddy *et al.*, 2005). Transformation of alfalfa leaf pieces was following co-cultivation with *A. tumefaciens*. Kanamycin resistance conferred by the *nptII* gene was used as a selectable marker. Transgenic alfalfa showed a range of differences in lignin content and composition. In cytochrome P450 transgenic alfalfa, lignin content was negatively related to rumen digestibility, but no relationship was observed between lignin composition and rumen digestibility (Reddy *et al.*, 2005).

Transgenic alfalfa plants containing the coumaroyl shikimate 3-hydroxylase (C3H) gene from *M. truncatula* in the antisense orientation were generated (Reddy *et al.*, 2005; Ralph *et al.*, 2006). The antisense C3H clone was driven by the vascular-specific bean PAL2 promoter and NOS 3' transcription terminator. *Agrobacterium*-mediated transformation was used to transform alfalfa leaf pieces. Selection of alfalfa transformants was achieved by kanamycin resistance conferred by the *nptII* gene. Down-regulation of C3H transcript in alfalfa altered lignin composition as the proportion of p-hydroxyphenyl (P) units was increased compared to the usually dominant G and S units of lignin. Transgenic alfalfa plants displayed improved digestibility values (Reddy *et al.*, 2005; Ralph *et al.*, 2006).

In a separate study, transgenic alfalfa contained caffeic acid 3-*O*-methyltransferase (COMT) and caffeoyl coenzyme A 3-*O*-methyltransferase (CCoAOMT) genes from alfalfa in antisense orientation (Guo *et al.*, 2001; Marita *et al.*, 2003). The transgenes were driven by the vascular-specific bean PAL2 promoter and NOS 3' transcription terminator. Alfalfa transformation was by co-cultivation of leaf pieces with *A. tumefaciens*. Kanamycin resistance conferred by the *nptII* gene was used as the selectable marker. Transgenic plants down-regulated for COMT showed reduced lignin content and altered lignin composition. Down-regulation of COMT transcript in transgenic alfalfa was accompanied by an increase in cellulose, resulting on average a 30% increase in cellulose:lignin ratio. Digestibility of transgenic alfalfa was also improved. On the other hand, lignin content in transgenic alfalfa down-regulated in the expression of CCoAOMT was reduced, but the structure of lignin was similar to that of nontransformed control plants. Nevertheless, a much greater improvement in digestibility values of alfalfa forage was reported for transgenic alfalfa down-regulated in CCoAOMT (Guo *et al.*, 2001).

Uridine diphosphate (UDP)-glucose dehydrogenase is a key enzyme in the biosynthesis of uronic acids. Uronic acids represent a large proportion of the primary cell wall matrix in plants. Samac *et al.* (2004a) reported the generation of transgenic alfalfa overexpressing a soybean UDP-glucose dehydrogenase gene in the sense direction. The transgene was driven by an Arabidopsis class III chitinase promoter

or an alfalfa phosphoenolpyruvate carboxylase promoter and NOS 3' transcription terminator. Transformation was following co-cultivation of leaf pieces with *A. tumefaciens* LBA 4404. Plant transformation vectors contained the *nptII* gene for selection of transformants by resistance to kanamycin. UDP-glucose dehydrogenase enzyme activity in transgenic lines grown in the greenhouse was up to sevenfold greater than in nontransformed control plants. However, enzyme activity of field-grown transgenic plants showed a maximum of 1.9-fold more enzyme activity than the nontransformed control plants. No significant increase in pectin or uronic acids was seen in the polysaccharide fraction of field-grown transgenic plants. However, lower cell wall polysaccharide content and mannose concentrations were accompanied by higher Klason lignin content in transgenic plants. Ectopic expression of UDP-glucose dehydrogenase showed a 15% increase in xylose content in stem tissues of most transgenic alfalfa lines.

2.2.2 Reducing protein loss for forage quality improvement

Ensiling is a popular method of preserving forage crops. Wounding of forage crop leaves during crop harvest and ensiling releases cellular proteases resulting in degradation of plant protein to small peptides and amino acids. Red clover (*Trifolium pratense* L.) experiences less protein loss than alfalfa when ensiled. Proteolytic inhibition of ensiled forage seen in red clover was hypothesized to occur through the activity of polyphenol oxidase (PPO) on endogenous *o*-diphenols. To test this idea, the *PPO* gene from red clover was placed under the control of a constitutive CsVMV promoter and NOS 3' transcription terminator to produce transgenic alfalfa (Sullivan *et al.*, 2004). Transformation of alfalfa leaf pieces was mediated by co-cultivation with *Agrobacterium* strain LBA 4404. Kanamycin resistance conferred by the *nptII* gene was used to select transformed alfalfa. The red clover PPO was expressed in transgenic alfalfa and the protein was shown to be active in alfalfa extracts, as evidenced by *o*-diphenol-dependant extract browning and quantitative assays of PPO activity (Sullivan *et al.*, 2004; Sullivan and Hatfield, 2006).

Leaf extracts of transgenic alfalfa showed a nearly fivefold *o*-diphenol-dependent decrease in proteolysis compared to those of nontransformed control alfalfa (Sullivan and Hatfield, 2006). In small-scale ensiling experiments, proteolysis was reduced for PPO-expressing transgenic alfalfa (Sullivan and Hatfield, 2006).

2.2.3 Improving dietary proteins in alfalfa forage

Most dietary proteins ingested by ruminants are rapidly degraded by rumen bacteria. Rumen microbial proteins in turn become sources of protein for the animals. However, microbial proteins are poor in sulfur amino acids. A small number of proteins appear to be relatively resistant to degradation in the rumen and presumably are assimilated by ruminants in the lower gastrointestinal tract. Ovalbumin, one such protein that is found to be resistant to degradation by rumen bacteria, is also regarded as nutritionally valuable. Schroeder *et al.* (1991) placed a chicken ovalbumin gene under the control of the CaMV35S promoter and NOS 3' transcription terminator to generate transgenic alfalfa plants. Transformation of alfalfa leaf pieces was done by co-cultivation with *A. tumefaciens* strain LBA 4404. Selection of transformed alfalfa was by kanamycin resistance conferred by the *nptII* gene. Transgenic alfalfa plants expressed the recombinant protein in leaf tissues and ovalbumin expression was estimated from 0.001% to 0.01% of total soluble protein. Recombinant ovalbumin expression was stable and was detected in leaf tissues of all ages (Schroeder *et al.*, 1991).

2.3 Abiotic Stress Tolerance

2.3.1 Overexpression of transcription factor to improve salinity tolerance

Transcription factors modulate gene expression patterns through sequence-specific DNA binding and/or protein-protein interactions. They are capable of acting as switches of gene expression regulatory cascades by activating or repressing transcription of target genes. One such gene, *Alfin1*, encodes a putative transcription factor

in alfalfa, and the recombinant protein binds DNA in a sequence-specific manner, including the promoter region of the salt (NaCl) inducible gene *MsPRP2* (Winicov and Bastola, 1999). *Alfin1*-binding sites were shown to occur in promoters of genes expressed in roots of a wide variety of plant species (Winicov, 2000). Transgenic alfalfa plants containing the alfalfa *Alfin1* cDNA (complementary DNA), in the sense or antisense direction, placed under the control of the CaMV 35S promoter and NOS 3' transcription terminator were generated (Winicov and Bastola, 1999). Transformation of alfalfa leaf pieces was *Agrobacterium*-mediated. Selection of transformant alfalfa was by kanamycin resistance conferred by the *nptII* gene. Transgenic calli and plant roots overexpressing *Alfin1* showed enhanced levels of endogenous *MsPRP2* mRNA (messenger RNA) accumulation. Calli overexpressing *Alfin1* were more resistant to growth inhibition by 171 mM NaCl than vector-transformed controls, whereas calli expressing *Alfin1* in the antisense orientation were more sensitive to NaCl inhibition. Similarly, transgenic plants overexpressing *Alfin1* showed salinity tolerance comparable to a NaCl-tolerant control plant (Winicov and Bastola, 1999). Further more, *Alfin1*-overexpressing transgenic alfalfa plants showed increased root growth under normal and salt stress conditions (Winicov, 2000). In contrast, the antisense transgenic plants grew poorly in soil, demonstrating that *Alfin1* expression is also essential for normal plant root development.

2.3.2 Overexpression of transcription factor to improve drought tolerance

The *WXP1* gene, an AP2 domain-containing putative transcription factor from *M. truncatula*, placed under the control of the CaMV 35S promoter and NOS 3' transcription terminator was used to transform alfalfa (Zhang *et al.*, 2005). Transformation of alfalfa leaf pieces was following co-cultivation with *A. tumefaciens* strain C58C1. Transformed lines were selected for resistance to the herbicide Basta conferred by the *bar* gene. Cuticular wax loading on leaves of transgenic alfalfa was significantly increased. The total leaf wax accumulation per surface area increased approximately 30–38% in the transgenic alfalfa

lines. Transgenic alfalfa leaves showed reduced water loss and chlorophyll leaching, as well as delayed wilting after watering was ceased and quicker and better recovery when the dehydrated plants were rewatered (Zhang *et al.*, 2005).

2.3.3 Improvement of tolerance to aluminum phytotoxicity in acid soils

Development of acid soils that limit crop production is an increasing problem worldwide. Many factors contribute to phytotoxicity of these soils, however, in acid soils with a high mineral content, aluminum (Al) is the major cause of toxicity. Toxicity can be reduced through lime application to raise soil pH, however, this amendment does not remedy subsoil acidity, and liming may not always be practical or cost effective. Addition of organic acids to plant nutrient solutions alleviates phytotoxic Al effects, presumably by chelating Al and rendering it less toxic.

In an effort to increase organic acid secretion and thereby enhance Al tolerance in transgenic plants, Tesfaye *et al.* (2001) produced transgenic alfalfa using the nodule-enhanced form of malate dehydrogenase (*neMDH*) gene from alfalfa. The *neMDH* gene in the sense direction was placed under the control of the CaMV 35S promoter and NOS 3' transcription terminator. Transformation of alfalfa leaf discs was *Agrobacterium*-mediated. Kanamycin resistance conferred by the *nptII* gene was used as the selectable marker. Malate dehydrogenase enzyme specific activity in root tips of selected transgenic alfalfa was 1.6-fold higher than in nontransformed control plants. A 4.2-fold increase in root concentration as well as a 7.1-fold increase in root exudation of citrate, oxalate, malate, succinate, and acetate was measured in transgenic alfalfa lines compared with nontransformed control alfalfa plants. In acid soils and hydroponic culture, transgenic alfalfa plants showed increased biomass accumulation compared to nontransformed control alfalfa.

2.3.4 Winter freezing tolerance

Transgenic alfalfa plants that overexpress manganese superoxide dismutase (Mn-SOD) cDNA

from alfalfa were produced (McKersie *et al.*, 1999). The transgene was driven by the CaMV 35S promoter and NOS 3' transcription terminator in the sense direction. Alfalfa petioles were transformed by co-cultivation with *A. tumefaciens*. Kanamycin resistance conferred by the *nptII* gene was used as the selection agent. In two field experiments, transgenic alfalfa plants showed over 25% better winter survival than the nontransgenic alfalfa controls (McKersie *et al.*, 1999).

Similarly, the Arabidopsis iron-superoxide dismutase (Fe-SOD) was expressed in transgenic alfalfa (McKersie *et al.*, 2000). The Fe-SOD cDNA was under the control of the CaMV 35S promoter and NOS 3' transcription terminator. Alfalfa petioles were transformed by co-cultivation with *A. tumefaciens*. Kanamycin resistance conferred by the *nptII* gene was used as the selection agent. Transgenic alfalfa plants overexpressing the Arabidopsis Fe-SOD transcripts showed greater survival after two winter seasons than the nontransformed control alfalfa plants (McKersie *et al.*, 2000).

2.4 Herbicide Resistance and Weed Control

In fall 2005, the first biotechnology-enhanced alfalfa, Roundup Ready[®] alfalfa, was commercialized in the United States. The plant transformation vector for this transgenic alfalfa contained an *Agrobacterium* gene encoding 5-enolpyruvylshikimate-3-phosphate synthase (EPSPS) fused to a transit peptide (Samac and Temple, 2004). The transgene was driven by a strong constitutive promoter and NOS 3' terminator (Samac and Temple, 2004). Transformation of alfalfa leaf discs was achieved by co-cultivation with *A. tumefaciens*. The transgenic alfalfa is resistant to glyphosate (active ingredient of Roundup herbicide). This trait is expected to provide growers with improved weed control and increased flexibility in timing of herbicide application.

2.5 Disease and Pest Resistance

As a potential strategy to improve disease resistance in plants, Masoud *et al.* (1996) generated transgenic alfalfa utilizing constitutive expression of chitinase and glucanase genes separately or

in tandem for coexpression. The acidic glucanase (*AgluI*) gene from alfalfa and the rice basic chitinase (*RCH10*) gene were placed under the control of CaMV 35S and NOS 3' transcription terminator. Plant transformation vectors contained each transgene separately, or in tandem for coexpression in a single transgenic plant. Transformation of alfalfa was by co-cultivation of leaf discs with *A. tumefaciens* strain LBA 4404. Selection of transformed alfalfa was by kanamycin resistance conferred by the *nptII* gene. Both transgenes were expressed in transgenic alfalfa plants. However, the level of expression of each transgene by transgenic alfalfa plants with both transgenes in tandem was much less than transgenic alfalfa plants carrying a single transgene. Only transgenic plants expressing *AgluI* displayed reduced disease symptoms from *Phytophthora megasperma* f. sp. *medicaginis* inoculations. Transgenic alfalfa plants did not tolerate infections from other fungi infections including *Stemphylium alfalfae*, *Colletotrichum trifolii*, or *Phoma medicaginis* (Masoud *et al.*, 1996).

Alfalfa mosaic virus (AMV) can cause significant yield losses to forage legumes. An AMV RNA 4 gene encoding the coat protein of AMV was placed under the control of the CaMV 35S promoter and T-DNA ORF 25 RNA terminator (Hill *et al.*, 1991). Transformation of alfalfa was by co-cultivation of leaf discs with *A. tumefaciens* strain LBA 4404. Selection of transformed alfalfa was by kanamycin resistance conferred by the *nptII* gene. Production of the coat protein by transgenic alfalfa plants ranged from <100 ng to nearly 500 ng coat protein per milligram soluble leaf protein. While nontransformed alfalfa plants showed systemic infections of the virus following inoculations with 10 $\mu\text{g ml}^{-1}$ AMV, transgenic alfalfa plants develop resistance to AMV with inoculations of up to 50 $\mu\text{g m l}^{-1}$ AMV (Hill *et al.*, 1991).

Phytocystatins, inhibitors of cysteine proteinases, are found in a number of plants where they may play a role in defense against pathogens and pests. The cDNAs of the phytocystatins of rice, oryzacystatin I (*OC-I*) and oryzacystatin II (*OC-II*), were expressed in transgenic alfalfa plants under the control of the *PinII* promoter (Samac and Smigocki, 2003). Transformation was by co-cultivation of leaf discs with *A. tumefaciens*. Transformants were selected by

kanamycin resistance conferred by the *nptII* gene. Populations of the root-lesion nematode (*Pratylenchus penetrans*) in alfalfa roots from one transgenic alfalfa line containing the *PinII::OC-I* transgene and one transgenic line containing the *PinII::OC-II* transgene were reduced by 29% and 32%, respectively, compared with a vector only transgenic control line (Samac and Smigocki, 2003).

2.6 Transgenic Alfalfa for Industrial Applications

Plants are capable of carrying out acetylation, phosphorylation, and glycosylation as well as other post-translational protein modifications required for the biological activity of many recombinant proteins. Indeed, numerous recombinant proteins have been produced in transgenic plants. Alfalfa has primarily been used as a source of forage and animal feed. Improving the economic value of forage legumes could be achieved by developing new uses and value-added products of these crops. The ease of genetic transformation and large-scale cultivation makes alfalfa suitable for production of recombinant proteins.

2.6.1 Production of biodegradable plastic

A biodegradable polymer, polyhydroxybutyrate (PHB), is made naturally by many bacteria under nutrient-limiting conditions, and can be produced commercially by fermentation (Saruul *et al.*, 2002). Three genes from *Ralstonia eutropha* required for PHB synthesis, *pha*, *phb*, and *phc*, were each placed between the CaMV 35S promoter and NOS 3' transcription terminator, in the same plant transformation vector. Alfalfa transformation was by co-cultivation of leaf discs with *A. tumefaciens*. Kanamycin resistance conferred by the *nptII* gene was used as the selectable marker. Polymer granules similar to bacterial PHB indicating the production of the bioplastic were observed in chloroplasts of transgenic alfalfa. The amount of PHB accumulation in transgenic alfalfa was estimated at approximately 0.025–1.8 g kg^{-1} dry weight. Transgenic alfalfa exhibited growth similar to nontransformed plants, and F_1 hybrid progeny, obtained from crosses of PHB transgenic plants

with elite alfalfa germplasm exhibited leaf PHB levels similar to the transgenic parental line.

2.6.2 Phytoimmunogen production in transgenic alfalfa

Vaccines produced in transgenic plants offer a system for oral delivery of recombinant immunogens. This approach is especially relevant when used for enteric pathogens since oral immunization may be capable of eliciting appropriate immune mechanisms for the induction of protective responses.

In an attempt to use alfalfa plants for vaccine production, a 96bp coding sequence for the bovine rotavirus VP4, eBRV4 peptide, fused with the *gusA* gene was driven by the CaMV 35S promoter and NOS 3' transcription terminator (Wigdorovitz *et al.*, 2004). Transformation of alfalfa petioles was *Agrobacterium*-mediated. Kanamycin conferred by the expression of the *nptII* gene was used as a marker gene for selection of transformants. The recombinant protein was shown to induce protective lactogenic immunity against a virulent rotavirus in suckling mice born from immunized adult female mice (Wigdorovitz *et al.*, 2004).

2.6.3 Production of industrially important enzymes and phytopharmaceuticals

In an effort to utilize transgenic alfalfa for the production of industrially useful enzymes, Austin *et al.* (1995) used an α -amylase gene from the bacterium *Bacillus licheniformis* to transform transgenic alfalfa. α -amylase is involved in starch degradation and the production of a recombinant protein using plants has potential industrial-scale applications in starch processing. The transgene was driven by the MAC promoter and mannopine synthase transcription terminator from *Agrobacterium*. The MAC promoter is a hybrid fragment that contains some elements from the CaMV 35S promoter and the nopaline synthase promoter from *Agrobacterium*. Transformation of alfalfa was by co-cultivation of leaf discs with *A. tumefaciens* strain LBA 4404. Selection of transformed alfalfa was by kanamycin resistance conferred by the *nptII* gene. Transgenic alfalfa

plants looked normal throughout the growth period, and recombinant protein expression was estimated in the range of 0.001–0.01% of total soluble protein extracts. Field-grown transgenic alfalfa plants also expressed the recombinant α -amylase enzyme with no effect on biomass production (Austin *et al.*, 1995).

Another recombinant enzyme that was produced using transgenic alfalfa was manganese-dependent lignin peroxidase (Mn-P) from the fungus *Phanerochaete chrysosporium* (Austin *et al.*, 1995). The objective was to produce a recombinant enzyme using plants for large-scale application as a bleaching agent in the biopulping process (Austin *et al.*, 1995). The transgenic alfalfa is also thought to improve digestibility of crude fiber as ruminant feed. The transgene was driven by the MAC promoter and mannopine synthase transcription terminator from *Agrobacterium*. Transformation of alfalfa was by co-cultivation of leaf discs with *A. tumefaciens* strain LBA 4404. Selection of transformed alfalfa was by kanamycin resistance conferred by the *nptII* gene. Expression of the recombinant protein was estimated in the range of 0.01–0.5% of total soluble protein extracts. Field-grown transgenic alfalfa plants also expressed the recombinant Mn-P protein with an estimated yield of up to 0.15% (high expressing plants) of total soluble protein (Austin *et al.*, 1995). Transgenic alfalfa plants expressing Mn-P looked normal for the first 2–3 weeks of growth, but high expressing plants showed foliar yellowing accompanied by stunted and slow growth rate.

Most phosphorus (P) in plants is stored as phytic acid, and phytic acid is not readily digested by monogastric animals, such as poultry and swine. To help overcome this problem, a phytase enzyme, secreted by *Aspergillus niger*, has been widely incorporated in animal feeds to help improve P availability by degradation of phytate. Ullah *et al.* (2002) reported the production of transgenic alfalfa carrying the *phyA* gene from *Aspergillus ficuum*. The transgene was driven by the MAC promoter and mannopine synthase transcription terminator from *Agrobacterium*. Transformation of alfalfa was by co-cultivation of leaf discs with *A. tumefaciens* strain LBA 4404. Selection of transformed alfalfa was by kanamycin resistance conferred by the *nptII* gene. The recombinant enzyme was recovered from alfalfa leaf tissues

and was found to be active and stable, with an approximate 17-fold increase in phytase enzyme activity values in leaves of transgenic alfalfa plants (Ullah *et al.*, 2002).

Production of transgenic plants that express cellulase enzymes are thought to have great potential for use in the conversion of lignocellulosic biomass to ethanol. Ziegelhoffer *et al.* (1999) produced transgenic alfalfa plants carrying the E2 and E3 cellulase genes of *Thermomonospora fusca* under the control of the MAC promoter and manopine synthase transcription terminator from *Agrobacterium*. Transformation of alfalfa was by co-cultivation of leaf discs with *A. tumefaciens* strain LBA 4404. Selection of transformed alfalfa was by kanamycin resistance conferred by the *nptII* gene. Recombinant cellulase expression by transgenic alfalfa plants ranged from 0.04% of total soluble protein for E3 cellulase to 0.1% of total soluble protein for E2 cellulase (Ziegelhoffer *et al.*, 1999).

The extraction and purification of proteins from biochemically complex plant tissues is a laborious and expensive process that presents a major limitation to large-scale protein production using transgenic plants. Exudation of recombinant proteins from roots may offer an alternative for use of alfalfa in the production of value-added phytopharmaceuticals. Transgenic alfalfa plants were produced following transformation with a fungal cDNA from *Trichoderma atroviride* encoding an endochitinase gene (*ech42*) fused in frame to the signal peptide of a white lupin acid phosphatase and under the control of the CsVMV promoter and NOS 3' terminator (Tesfaye *et al.*, 2005). Plant transformation vectors were introduced into alfalfa by *Agrobacterium*-mediated transformation. Kanamycin resistance was used as the selectable marker for transformed alfalfa. Chitinase mRNA and protein synthesis in transformed plants was accompanied by chitinase enzyme activity. The recombinant ech42 enzyme was secreted into the rhizosphere. Chitinase activity in root exudates of transgenic alfalfa was 7.5–25.7 times higher than in the nontransformed control alfalfa plants. The secreted recombinant endochitinase retained its lytic activity against glycol chitin substrate and also showed antifungal activity by inhibition of spore germination of two fungal pathogens.

2.6.4 Phytoremediation of herbicide contaminated soils

Atrazine is one of the most widely used herbicides in the United States. In specific Gram-negative soil bacteria, atrazine chlorohydrolase (*atzA*) is the first enzyme in a pathway that catalyses the hydrolytic dechlorination and detoxification of atrazine to hydroxyatrazine. The potential of transgenic alfalfa expressing an *atzA* gene to take up, dechlorinate, and detoxify atrazine was investigated (Wang *et al.*, 2005). Transgenic alfalfa plants were generated containing an *atzA* gene modified for plant expression, *p-atzA*, under the control of the CsVMV promoter and NOS 3' transcription terminator. Plant transformation vectors were introduced into alfalfa following co-cultivation of leaf discs with *A. tumefaciens* strain LBA 4404. Kanamycin resistance conferred by the *nptII* gene was used as the selectable marker for transformed alfalfa. Transgenic alfalfa plants expressing *p-atzA* grew over a wide range of atrazine concentrations. Thin layer chromatography analyses indicated that *in planta* expression of *p-atzA* resulted in the production of hydroxyatrazine. Hydroponically grown transgenic alfalfa dechlorinated atrazine to hydroxyatrazine in leaves, stems, and roots (Wang *et al.*, 2005).

3. FUTURE ROAD MAP

3.1 Expected Products

The development and commercialization of Roundup Ready® alfalfa has paved the way for development of additional biotechnology-derived traits in alfalfa. However, the traits developed must be of high economic value in order to recover the considerable costs of developing and releasing transgenic crop varieties. Because alfalfa is used primarily for livestock feed, the direct value of a biotechnology-derived trait would be targeted to the producer of alfalfa or livestock, rather than to the general public. Traits of interest to livestock producers include increasing forage digestibility and decreasing the potential for bloat. Recently, significant advances have been made to reduce the lignin content and/or composition of alfalfa to increase digestibility (Guo *et al.*, 2001; Marita

et al., 2003; Reddy *et al.*, 2005; Ralph *et al.*, 2006). Additionally, a greater understanding of the genes for proanthocyanidin (condensed tannin) production has been achieved (Ray *et al.*, 2003; Xie *et al.*, 2003), which will accelerate the development of bloat-safe alfalfa. Forage yield is of primary importance to alfalfa producers. A significant decrease in leaf senescence, with a concomitant delay in plant flowering, has been achieved by controlled expression of isopentenyl transferase, an enzyme involved in cytokinin biosynthesis (Gan and Amasino, 1995; Sandman *et al.*, 2003). In addition to potentially increasing yields, a delay in flowering will provide producers with greater flexibility in crop harvest. Enhancing crop adaptation, such as tolerance to salt, cold, or acid soils using transgenic approaches may not have the economic return for commercializing these traits.

3.2 Risks and Concerns

Alfalfa is an insect-pollinated crop; therefore, safeguards are needed to ensure trait purity of the biotechnology-derived trait and to mitigate the dissemination of a regulated trait. Field studies were conducted in the seed-producing areas of Canyon County, Idaho using leaf cutter bees (Fitzpatrick *et al.*, 2003) and Kings County, California using honeybees (Teuber *et al.*, 2004) to measure pollen flow. Based on these studies, 1.6 km minimum isolation for production of Roundup Ready® alfalfa seed was established.

3.3 Expected Technologies

Transformation of alfalfa chloroplasts, via optimization of biolistic transformation, would facilitate development of specific biotechnology-derived traits. Chloroplast transformation in other crops has been shown to increase gene copy number and protein production. Enhanced product accumulation would be useful in production of vaccines and other high value proteins. In addition, retaining some protein products, such as cell wall hydrolases, within the chloroplast may protect the cell from deleterious effects of production. Finally, the chloroplast is an ideal location for synthesis of some biopolymers, such as polyhydroxyalkanoates. Because chloroplasts are

found in alfalfa pollen, chloroplast transformation would not be a means of managing trait dissemination.

1. INTRODUCTION

1.1 History, Origin, and Distribution

The true clovers (*Trifolium* spp.), may have been cultivated in Europe as early as the 4th Century AD (Zohary and Heller, 1984), but largely remained wild until around 1000 AD when they were domesticated in Spain. By the 17th century, clovers, accompanied by rhizobial bacteria and honeybees as pollinators, had spread throughout Europe where they were to change the world by providing the nitrogen (N) that drove the agricultural revolution of the 18th and 19th centuries (Kjaergaard, 2003). This co-evolved plant-bacterium-insect species association provided the basis of a human population explosion and literally transformed 18th century landscapes into scenes flowing with milk and honey. Interestingly, after the 1940s, and the high-energy mass production of nitrate fertilizers, clovers progressively declined, first in the northern hemisphere, and later in the southern hemisphere. In the 21st century, they are poised to return for widespread use again as the age of cheap oil and abundant energy come to an end (Kjaergaard, 2003).

A recent DNA sequence phylogenetic analysis (Ellison *et al.*, 2006) revealed that the genus *Trifolium* is monophyletic with three major centers of diversity—the Mediterranean basin, western North America, and the East African

highlands. Of these, the Mediterranean center has the most species and is the likely location of origin of the genus. The American species apparently arose from a single origin while the African species may have arisen from three separate dispersals. The genus has approximately 250 species, of which about 15 have been widely commercialized for agriculture (Zohary and Heller, 1984). The most important perennial pastoral species are red clover (*Trifolium pratense* L.) and white clover (*Trifolium repens* L.). There are several important annual clovers, including berseem (*Trifolium alexandrinum* L.), Persian clover (*Trifolium resupinatum* L.), and subterranean clover (*Trifolium subterraneum* L.) that are used as cool season annuals in many countries and a number of species with minor agricultural use in various countries (Taylor, 1985). To date, red, white, and subterranean clovers have been the main targets of forage biotechnology.

Red clover appears to have originated in Southeast Europe and Asia Minor (Smith *et al.*, 1985). The species became widespread throughout Eurasia and is morphologically highly variable as the result of the development of locally adapted ecotypes. It has become one of the most widely used species in temperate agriculture. *T. repens* is even more widespread than *T. pratense*. It is naturally distributed throughout Europe, northern and Central Asia, all Mediterranean countries, and northern Africa. It has been introduced into

many other countries where it is cultivated and often provides excellent grazed feed because of its prostrate habit. It is one of the best honey plants known.

1.2 Botanical Descriptions

Over 80% of *Trifolium* species evaluated by DNA phylogeny have $2n = 2x = 16$ chromosomes and $x = 8$ is the confirmed basic number for *Trifolium* (Ellison *et al.*, 2006). However, *T. pratense* ($2n = 2x = 14$, Section *Trifolium*) has the reduced basic number $x = 7$. White clover is one of very few allotetraploids in *Trifolium* ($2n = 4x = 32$), and is classified in section *Trifoliastrum* with 16 other taxa that are predominantly $x = 8$. A recent DNA sequence phylogeny (Ellison *et al.*, 2006) revealed that the alpine species *Trifolium pallescens* may be a progenitor, perhaps in combination with *Trifolium occidentale*. However, this is yet to be verified.

Red clover grows from a thick root and a short crown that produces branched stems that do not usually root from the nodes, although some “stoloniferous” forms with nodal rooting have been described (Smith and Bishop, 1993; Rumball *et al.*, 2003). The rootstock may last for many years in some environments, but in many situations, especially under frequent grazing, it can become damaged or diseased after 2–5 years. Consequently, it is a short-lived perennial. Red clover is adapted to slightly acid to neutral, free-draining soils with good water-holding capacity and it will not tolerate waterlogging. *T. pratense* is seen growing in meadows, on roadsides, forest clearings, and near water in moist regions worldwide. It requires adequate P and potassium (K) to maintain production. Populations are highly polymorphic for flowering requirements, varying in need for cold treatment and critical photoperiod. Zohary and Heller (1984) provided a tentative and incomplete subdivision of the species into six varieties.

White clover is tap rooted in its first year or 18 months of seedling growth, and produces indeterminate stolons that root at the nodes and branch in the leaf axils (Thomas, 1987a, b). White clover is found in pastures throughout the temperate world with annual rainfall >500 mm. During flowering, inflorescences replace vegetative

branches in some leaf axils. After the death of the tap root, survival and growth become dependent on stolon fragments with nodal roots (Beinhart, 1963). These roots are usually shallow and less robust than the seedling tap root and the plant fragments can be vulnerable to soil surface drying and to pests and diseases. As a consequence, a white clover plant has two growth phases and it can appear to be relatively hardy as a seedling but much less so in its adult fragmented form. As a creeping plant, white clover is a colonizer for which no part survives for more than 12–15 months. Consequently, although it is perennial, it has been described as a “rolling annual” (Hollowell, 1966). It is intolerant of drought, excess water, salinity, and highly alkaline and acid soils (Gibson and Cope, 1985; Williams, 1987a). Flowering requirements vary among populations and greatly among individuals within populations (Thomas, 1987c). Inflorescence initiation is generally promoted by long days but is also affected by low temperatures. Many populations appear to behave as short-long day plants. Much of the seed is hard and can remain in soil seed banks for many years (Harris, 1987). The dual mechanisms of asexual reproduction by stolon proliferation and sexual reproduction through seeds give white clover adaptation to a wide range of habitats.

Both red and white clovers have relatively small genome sizes, red clover having a 1C haploid nuclear genome value of 0.7–0.8 pg (picogram) and white clover 1.0–1.5 pg (Bennett and Smith, 1991). Red clover has regular diploid cytological behavior. White clover is a diploidized allotetraploid and behaves very regularly at meiosis to produce 16 bivalents almost without exception. Inheritance is as a typical amphidiploid. Thus, homeoloci that are present in both subgenomes, for example, shikimate dehydrogenase (SDH), are inherited totally independently, as if the other locus was not present (Williams *et al.*, 1998). Several important traits are conditioned by loci that are present in only one of the subgenomes and are inherited in diploid fashion, for example, the S-incompatibility system, cyanogenesis, V leaf marks (Williams, 1987c). Despite being allotetraploid, the white clover karyotype has only two nucleolar organizer regions (NORs). Cytogenetic fluorescent *in situ* hybridization (FISH) mapping of multigene DNA sequences coding for 18S-5.8S-26S rDNA

(ribosomal DNA) and 5S rDNA in white clover showed that at least one pair of ancestral NORs had been eliminated (Ansari *et al.*, 1999). The 18S-26S rDNA (NOR) was located proximally on the shorter arm of a submetacentric chromosome pair, which also carried a 5S rDNA locus on the longer arm. A second 5S rDNA locus occurred proximally on the longer arm of another submetacentric chromosome pair. White clover and its closest relatives share a unique centromeric repetitive DNA sequence, TrR350 (Ansari *et al.*, 2004).

1.3 Economic Importance

Clovers continue to have major economic importance internationally despite a downturn in use since about 1950 coinciding with the availability of abundant N fertilizers. White clover seed production is currently around 15 000 MT annually, with approximately 4000 MT of this from New Zealand, 1600 MT from Europe, and the bulk from North America. White clover is also the most important legume of grazed pastures, not only in moist temperate (rainfall >750 mm) areas, where it is best adapted, but also on acidic soils in semi-arid regions where it serves as the best legume for grazing. White clover is found on 7.8 million hectares of pasture in Australia (Australian Government, 2004) and 9 million hectares in New Zealand grasslands (Williams, 1983). Its value to New Zealand alone has been estimated to be in excess of US\$2 billion annually (Caradus *et al.*, 1996), and the dairy industry of the state of Victoria, Australia, is estimated to benefit annually by A\$267 million (Mason, 1993).

In general, red clover is better adapted to forage production under cutting for hay or silage while white clover has adaptations that best suit it for grazing. However, both species are highly polymorphic and there are prostrate red clover types suitable for grazing and tall, upright white clovers (e.g., ladino clover) suitable for cutting. Clovers have very high nutritional value for livestock compared to pasture grasses (Essig, 1985; Abberton *et al.*, 2002). Animal performance on white clover is substantially greater than that on temperate grasses as a consequence of high voluntary intake and high quality (Ulyatt, 1970).

Honey production is a very important secondary use of white clover.

Red clover uniquely contains a polyphenol oxidase (PPO) enzyme, which reduces protein breakdown and leads to approximately 40% less proteolysis during ensiling and rumen digestion than other legume forages (Albrecht and Muck, 1991; Jones *et al.*, 1995a, b, c). This leads to larger amounts of intact forage protein passing from the rumen to the intestine and thus red clover is more efficiently utilized by grazing animals (Buxton, 1996). However, red clover contains phyto-oestrogenic isoflavones, which can cause severe reproductive problems in sheep. These isoflavones include biochanin, diadzein, formononetin, and genistein, the most important of which is formononetin (Morley *et al.*, 1966, 1968). Selection for reduced formononetin has been successful (Rumball *et al.*, 1997) and has reduced ewe fertility problems (McDonald *et al.*, 1994). Products such as Promensil, based on red clover extracts, contain isoflavones, which are strong antioxidants and oestrogens. These are being produced as dietary supplements to combat PMS, osteoporosis, and high cholesterol in humans.

1.4 Traditional Breeding

1.4.1 Red clover breeding

Red clover has a gametophytic incompatibility system based on *S*-alleles (Townsend and Taylor, 1985). Self-fertile mutants occur and some selfing also occurs when the incompatibility system fails. This ensures that cross-pollination predominates and that populations consist of highly heterozygous plants. Breeding, therefore, aims to select plants that produce high frequencies of desirable plants in progenies from interpollination with other plants. Selection of red clover thus involves progeny testing of elite parent plants, and varieties are synthetic populations developed by intercrossing in all possible combinations (polycrossing). Inbred lines can be maintained either vegetatively or sexually and higher yielding single or double cross hybrids are theoretically possible (Cornelius *et al.*, 1977), but high yielding hybrids have proved difficult to achieve because of difficulties in obtaining superior inbred lines.

Mutation breeding has been used little in red clover, partly because of the vast amount of genetic diversity already present and partly because the self-incompatibility system that limits the expression of recessive mutations. Chromosome doubling to produce tetraploid varieties with superior yields has been successfully used in several countries but the polyploids can also show low seed yields because of pollination problems (Cope and Taylor, 1985).

Ex situ genetic resources of red clover are extensive. Large collections exist in the United States Department of Agriculture (USDA)-GRIN system and the European Union with smaller collections elsewhere. Further collections are needed, especially in regions of diversity such as eastern Europe, Turkey, Iran, and Iraq, where populations are coming under threat of extinction due to pressures of human population growth. There is considerable genetic diversity for plant type in red clover, from prostrate and creeping, to very tall upright plants and availability of appropriate types for particular end uses (single cut, double cut, grazed pastures, etc.) is a problem mainly where long-lived perennials are desired. Red clover grows strongly in the spring through to late summer and generally grows slowly in the cool seasons. Some Mediterranean-type germplasm from Morocco was found to have cool season activity and these were hybridized with the New Zealand material (of European origin) to produce new varieties for use in maritime climates (Claydon *et al.*, 1993). Persistence continues to be a major breeding objective in most breeding programs. Plants with the crown below the soil surface instead of above may have more longevity (Smith, 2000), as would plants with disease-resistant tap roots that also have large secondary root systems. To date, plants with strong secondary roots or rhizomes have not been found and use of the secondary gene pool (i.e., related species) may be fruitful in this regard. Use of alternative species through interspecific hybridization is likely to contribute to heat, drought, and cold tolerance. The major pests and diseases of red clover vary with region and include the usual spectrum of foliar and root diseases, viruses, insects, and nematodes (e.g., Smith *et al.*, 1985; Smith, 2000). Those that shorten the life of the crown and root are particularly important.

The feed value of red clover has been the subject of some breeding effort. Attempts have been made

to find plants with proteins more resistant to degradation (Broderick *et al.*, 1991), while another approach would be to increase the content of soluble carbohydrates that would provide energy for rumen microorganisms to break down proteins without wasteful ammonia production. In this context, genetic variation for cell wall pectins in red clover has been detected (Hatfield and Smith, 1995). Selection for low formononetin has proved to be important for sheep grazing (McDonald *et al.*, 1994; Rumball *et al.*, 1997). On the other hand, now that red clover has become a source of industrial pharmaceuticals (isoflavones), selection for increased contents of such constituents is equally likely to be important.

Seed yield and high persistence tends to be negatively correlated in red clover (Steiner *et al.*, 1997; Herrmann *et al.*, 2006). This has proved to be a barrier to the commercialization of creeping types, in particular, and the development of persistent varieties with high seed yields remains as an important objective for future breeding.

Framework linkage maps of red clover have been developed by Isobe *et al.* (2003), Sato *et al.* (2005), and Herrmann *et al.* (2006). The latter authors identified 38 quantitative trait loci (QTLs) for eight seed yield components as a step toward the application of marker-assisted breeding for improved seed yields. To date, continuous progress in red clover performances through conventional breeding has occurred. Woodfield (1999) has estimated that genetic gains from red clover breeding in New Zealand have been approximately 1% per year since breeding began.

1.4.2 White clover breeding

White clover is a tetraploid but has a diploid system of gametophytic self-incompatibility involving oppositional *S*-alleles at a single locus. Consequently it is highly heterozygous and, having two independently assorting subgenomes, has intergenomic heterozygosity as well. It is severely affected by inbreeding (Cousins and Woodfield, 2006). Genetically, white clover behaves as a cross-pollinated diploid and varieties are generally structured similarly to those of red clover. As with red clover, single and double cross hybrids theoretically have high potential, although obtaining large numbers of suitable inbred lines for efficient screening is a

difficulty. Self-fertility alleles (*Sf*) have proved to be useful in this regard (Cousins and Woodfield, 2006). Because it is predominantly used as a grazing plant in conjunction with grasses, breeders in New Zealand (Caradus *et al.*, 1991) and, more recently elsewhere (Annicchiarico, 2003; Bouton *et al.*, 2005), have very successfully screened breeding populations under grass competition.

Mutation breeding is not a viable option for most objectives because of the tetraploid and outcrossing nature of the species. The diploid self-pollinating relative, *T. occidentale* has been developed as a possible genetic model for white clover (Jones *et al.*, 2006; Williams *et al.*, 2006a). This species has been successfully mutagenized and some stable condensed tannin-lacking mutants have been produced (Williams *et al.*, 2006a). Polyploidy has been explored in white clover and, although some hexaploid and octoploid families have been tested, cytological problems have occurred and the performance of the polyploid materials has not been adequate to make this approach attractive (Williams, 1987c). White clover is very widespread geographically and ecologically and is easy to collect because the seed heads can remain in place for long periods without completely shattering. Consequently, there are large numbers of accessions in seed banks worldwide. Some of the closely related species (Ellison *et al.*, 2006) carry traits that may benefit white clover and use of this secondary gene pool is a promising approach. A major weakness is the adult plant root system and strongly rooted related species like *Trifolium uniflorum* (Pandey *et al.*, 1987) and *Trifolium ambiguum* (Williams and Verry, 1981), which can hybridize with white clover, offer potential solutions. Intolerance to dry conditions is another weakness that might be corrected by hybridization with *T. ambiguum* (IGER) or *T. uniflorum* (Williams *et al.*, 2006b). *T. occidentale* could be a source of drought and salt tolerance and *Trifolium nigrescens* a source for heat and pest resistance (Hussain *et al.*, 1997). Other close species, which have as yet unknown attributes, include *Trifolium thalii* and *T. palleescens* (Williams *et al.*, 2006b).

White clover populations have traditionally been classified according to leaflet size as this trait is highly correlated with other organ sizes (e.g., stolon thickness) and with ecological fitness. Small-leaved plants are best adapted to closely

defoliated pastures, whereas larger-leaved types can be intolerant of hard grazing (Williams, 1987b). One of the most significant recent advances has been the development of large-leaved varieties that can withstand grazing pressures. This is exemplified by the breeding of Kopu II (Woodfield *et al.*, 2001) by selection under sheep grazing. The key methods used were to combine the genomes of small-, medium-, and large-leaved populations to develop parent plants with high stolon densities that survived under grazing pressures in combination with companion grasses. As a result, the old perceptions about a negative relationship between leaf size and grazing tolerance have been changed, although large-leaved varieties are still unlikely to persist under heavy sheep grazing. Use of diverse germplasm has also led to gains in yield and disease resistances in medium-leaved and medium-large-leaved varieties, for example, Crusader (Woodfield *et al.*, 2001).

Root thickness in white clover is correlated with leaf size so that plants with large leaves tend to have thicker roots (Caradus, 1977). Attempts to break this relationship by looking for thicker roots in smaller-leaved varieties have shown only limited success (Woodfield and Caradus, 1987). It is possible that, if a less fibrous, more thickened root system could be developed for adult white clover, the zone of adaptation of the species could potentially be extended to regions with hot, semi-arid climates. This would best be associated with improved drought tolerance of the shoot tissues. White clover generally grows most rapidly in spring and early summer and its cool season activity is low. The use in the 1960–1970s of Mediterranean germplasm to improve cool season activity especially in the United Kingdom, Australia, and New Zealand is well documented (Williams, 1987c).

White clover is affected by a wide range of pests and diseases (Gaynor and Skipp, 1987; Latch and Skipp, 1987; Skipp and Gaynor, 1987). The most intractable of these are the viruses and insects. The succulent nature of white clover tissue makes it a soft target for chewing insects. To date, no selection for resistance to chewing insects has been successful. Although some excellent advances in breeding for virus resistance have occurred by traditional breeding (Taylor *et al.*, 1995), viruses remain one of the main sources of yield losses in pastures (Barnett and Diachun, 1985; Garrett, 1991).

White clover requires high soil concentrations of phosphate to grow and fix N. Most soils require phosphate fertilizers, which are manufactured from nonrenewable resources that are progressively becoming harder to obtain and more expensive. Considerable effort has been allocated to identification and selection of plants able to grow efficiently at low soil phosphate concentrations but, despite promise, selections did not hold up in the field (Caradus, 1990; Caradus *et al.*, 1992). For both red and white clovers, advances in N-fixation potential have paralleled advances in yield. To date, no method has been developed that successfully disconnects N fixation from yield in the clovers. However, there is significant variation in white clover-*Rhizobium* associations for response to high soil N (Crush and Caradus, 2001) to suggest that the amount of N fixation at high soil N concentrations could be raised or lowered by selection. A more rapid "turning off" of N fixation at moderate soil N concentrations might provide a better grassclover balance by preventing clover elimination from mixed sward due to competition from grasses fed by fixed N.

Framework linkage maps for white clover and its very close diploid model species, *T. occidentale*, are available and marker-assisted approaches to clover improvement are in progress internationally. A set of simple sequence repeat (SSR) markers was characterized by Kolliker *et al.* (2001) and these were used by Jones *et al.* (2003) along with amplified fragment length polymorphism (AFLP) markers to develop a map of 18 linkage groups. Barrett *et al.* (2004), Griffiths *et al.* (2006), and Zhang *et al.* (2006) have reported SSR-based maps with 16 linkage groups with high levels of colinearity with *Medicago truncatula*, while Griffiths *et al.* (2006) have shown that the *T. occidentale* map is highly syntenic with *T. repens*. Using these maps, QTL analyses for agronomic traits have been carried out by Barrett *et al.* (2005) and Cogan *et al.* (2006).

Future breeding objectives for white clover include attention to forage quality. As indicated above, white clover is too low in soluble carbohydrate to enable efficient ruminant digestion of the relatively high protein it carries. Potentially large differences have been found among white clover varieties for soluble carbohydrate content, larger-leaved varieties tending to be higher than smaller-leaved varieties (Woodfield *et al.*, 2001).

Thus, it may be possible to select new varieties with higher soluble sugars that will be more efficiently utilized by grazing animals. White clover does not have high foliar concentrations of phyto-oestrogens but many populations are polymorphic for cyanogenesis. The basic genetics of cyanogenesis is well understood (Corkill, 1942; Williams, 1987c), but some aspects of its inheritance still need clarification. Highly cyanogenic varieties, for example, Grasslands Huia, have been used internationally for decades with few negative effects on grazing animals. Cyanogenic white clover may, however, be unsuitable for rapidly growing young animals during pregnancy (Gutzwiller, 1993).

Condensed tannins (CTs) have been targeted as a mechanism for solving the dual problems of bloat and inefficient protein degradation in the rumen since Jones and Lyttleton (1971) noted their potential. White clover has floral CTs but lacks them in leaf tissues. To date, efforts to obtain foliar CTs in red and white clover have been unsuccessful, and this remains a very desirable future breeding target.

Very significant advances in white clover performance through conventional breeding continue to be made. Genetic gains from New Zealand white clover breeding from 1985 to 1998 have been more than 4% annually for sheep grazing and 2.5% for cattle grazing. These gains come at the end of a 60-year breeding program in which mean annual gains have exceeded 1%, in line with many crop species (Woodfield, 1999).

1.5 Limitations of Conventional Breeding and Rationale for Transgenic Breeding

Relative to most field crop species, the clovers are comparatively undomesticated and not far removed from the wild genetic state. Therefore, they are still responding well to conventional breeding methods. In addition, white clover breeders, in particular, have hardly begun to use the secondary gene pools available in closely related species. Conventional breeding of clovers is thus a long way from reaching its limits. Nevertheless, there are some targets that are already looking to be intractable using conventional sources of genetic diversity and transgenics may provide faster solutions. Both insect and virus resistances are important targets that may be successfully

addressed through transgenic breeding. The addition of foliar CTs to clovers and PPO activity to white clover are potentially important nutritional objectives that may best be approached using genetic modification. Similarly, there have been difficulties to date using conventional breeding to improve the efficiency of the N-fixation system and the efficiency of use of phosphorus by clovers. Clover has lower water-soluble carbohydrate concentrations. These low soluble carbohydrate contents, in combination with high protein, can lead to wastage of protein N in ruminant animals where energy is required to prevent the conversion of ammonia to urea and excretion in urine (Buxton, 1996). Perhaps transgenics might eventually prove to be a useful approach for clover development.

2. DEVELOPMENT OF TRANSGENIC CLOVERS

2.1 Promoters for Transgenic Clovers?

There have been several attempts to evaluate potential promoters for transgenic clover transgenic research. The promoter of the *MtHP* gene, belonging to the *PR10* gene family, from *M. truncatula* was fused to the reporter *gusA* gene and nopaline synthase (NOS) transcription terminator to characterize its expression in transgenic white clover plants (Xiao *et al.*, 2005). Transformation was achieved by co-cultivation of cotyledons of imbibed seed with *Agrobacterium tumefaciens*. Selection of transformants was done via the herbicide phosphinothricin resistance conferred by the *bar* gene sequence encoding the enzyme phosphinothricin acetyltransferase. Strong constitutive β -glucuronidase (GUS) expression was observed in transgenic white clover plants containing the *MtHP* promoter. The level of GUS activity in transgenic white clover containing the *MtHP* promoter was higher than the level of GUS activity in transgenic clovers transformed with the cauliflower mosaic virus (CaMV) 35S promoter (Xiao *et al.*, 2005).

The efficacy of four promoter sequences from *Arabidopsis thaliana* (*atmyb32*, *adh*, *xero2*, and *SAG12*) was assessed in transgenic white clover (*T. repens*) plants generated by *Agrobacterium*-mediated transformation (Lin *et al.*, 2003). The promoters were fused to the β -glucuronidase

gene and NOS 3' transcription terminator (Lin *et al.*, 2003). The *atmyb32* promoter directed GUS expression in leaf and root vascular tissue including lateral roots and nodules with low levels of GUS expression in reproductive organs. Wound response of the *atmyb32* promoter in white clover leaves and stolons was also shown. The *adh* promoter showed anaerobic stress and dehydration stress response. The *xero2* promoter directed strong expression in roots, leaf vascular tissue, inflorescences, anther filaments, and pollen grains. The *SAG12* promoter resulted in senescence-associated GUS expression in transgenic white clover leaves (Lin *et al.*, 2003).

Genomic sequences comprising the 5'-UTR and promoter regions of the 1-aminocyclopropane-1-carboxylate (ACC) oxidase gene (TR-ACO1p, TR-ACO2p, TR-ACO3p, and TR-ACO4p) from white clover were fused to the β -glucuronidase gene and NOS 3' transcription terminator (Chen and McManus, 2006). The constructs were used to transform white clover cv. Huia by co-cultivation with *A. tumefaciens* strain LBA 4404 (Chen and McManus, 2006). Selection of transformants was done via kanamycin resistance conferred by the *nptII* gene sequence. The TR-ACO1 promoter directed the highest GUS expression in the apical tissues, axillary buds, and leaf petiolules in younger tissues and then declined in the ageing tissues. The TR-ACO2 promoter directed GUS expression in both younger, mature green, and in ontologically ageing tissue. The TR-ACO3 and TR-ACO4 promoters directed expression in the ontological older tissues, including the axillary buds and leaf petiolules. All promoters directed GUS expression in the ground meristem tissue of axillary buds, vascular tissue, pith and cortex of the internode and node, and the cortex and vascular tissue of the leaf petiolule (Chen and McManus, 2006).

Transgenic *T. repens* cv. Haifa was produced following transformation with a 1764 bp tobacco basic chitinase promoter driving the β -glucuronidase gene and NOS 3' transcription terminator (Pittock *et al.*, 1997). Transformation was achieved by co-cultivation of cotyledons of imbibed seed with *A. tumefaciens*. The *bar* gene and phosphinothricin selection was used to screen transformants. In transgenic clover plants, strong GUS expression was observed in tap and lateral root meristems. No GUS expression was detected in the pericycle or in the dividing cells of the developing lateral root. Also, mechanical

wounding and aphid (Family Aphididae) feeding resulted in rapid and localized GUS staining (Pittock *et al.*, 1997).

2.2 Improving Clover Forage Quality

Transgenic white clover plants generated by Jenkins *et al.* (2002) contained the gene encoding fructosyltransferase (Ftf) enzyme from the bacterium *Streptococcus salivarius*. The transgene was cloned between the CaMV 35S promoter and NOS 3' transcription terminator. Clover cotyledons were transformed by co-cultivation with *A. tumefaciens* strain AGL1. Selection of clover transformants was by kanamycin resistance conferred by the *nptII* gene. White clover does not normally accumulate fructan as a storage carbohydrate. However, transgenic clover plants accumulated fructan in leaves, petioles, stolons, flowers, and root tissues. Levels of fructan up to approximately 2% dry weight were measured in leaves. Ftf enzyme activity up to 120 nmol min⁻¹ g⁻¹ fresh weight was determined in leaf extracts of the transformed plants, and appeared to be stable throughout leaf development. Most transgenic white clover lines flowered and produced seeds, but the growth rate of some transformed lines decreased. In a transgenic line with relatively low fructan, levels of endogenous carbohydrates such as hexoses, sucrose, and starch were not substantially changed. However, growth and endogenous carbohydrate contents were reduced in transgenic white clover with relatively high fructan accumulation (Jenkins *et al.*, 2002).

Most dietary proteins ingested by ruminants are rapidly degraded by rumen bacteria. Rumen microbial proteins in turn become sources of protein for the animals. However, microbial proteins are poor in sulfur amino acids. A small number of proteins appear to be relatively resistant to degradation in the rumen and presumably are assimilated by ruminants in the lower gastrointestinal tract. In an attempt to improve the rumen-protected level of the sulfur amino acids cysteine and methionine in transgenic clovers, Christiansen *et al.* (2000) introduced the coding sequence of the sunflower seed albumin (SSA) into *T. repens* cv. Haifa by *A. tumefaciens*-mediated transformation. The SSA gene was driven by three different promoters in separate plant transformation vectors. The promoters used in this work

were: (1) the promoter region of the small subunit of ribulose biphosphate carboxylase (Rubisco) gene from *A. thaliana* (*A(ssu)*), (2) the promoter region of the small subunit of Rubisco gene of *Medicago sativa* (*L-ssu*), or (3) the commonly used CaMV 35S promoter. Transformant clovers were selected on the basis of their resistance to the herbicide phosphinothricin conferred by the *bar* gene sequence. The highest observed level of SSA accumulation in transgenic clovers was approximately 0.1% of total extractable leaf protein. Promoter activity as measured by the effect on the level of SSA accumulation was in the order of *A(ssu)* > CaMV 35S > *L-ssu* (Christiansen *et al.*, 2000).

In a separate attempt, a gene encoding a sulfur-rich maize seed storage protein, δ -zein, was introduced into white clover plants by *Agrobacterium*-mediated transformation of cotyledons with or without the apical shoot (Sharma *et al.*, 1998). The transgene construct was under the control of the double 35S promoter of CaMV and the NOS 3' transcription terminator. Selection of clover transformants was by kanamycin resistance conferred by the *nptII* gene. Transgenic clover plants expressed the maize δ -zein mRNA (messenger RNA) and protein in their leaves. The δ -zein protein was also detected in petioles, nodes, internodes, roots, and seeds of transgenic clover plants. In the highest expressing transgenic clover plants, δ -zein accumulation increased with increasing leaf age from 0.3% (young leaves) to 1.3% (old leaves) of total water-soluble protein (Sharma *et al.*, 1998).

Similarly, a transgene encoding the pea albumin 1 (PA1) protein, rich in sulfur amino acids, transcribed from the CaMV 35S promoter and NOS 3' transcription terminator was introduced into the white clover genotype WR8 via *Agrobacterium*-mediated transformation (Ealing *et al.*, 1994). By introducing genes encoding rumen-protected proteins rich in essential amino acids, the objective was to improve the quality of white clover proteins. Transgenic clover plants expressed and accumulated PA1 gene products (Ealing *et al.*, 1994).

2.3 Herbicide Resistance and Weed Control

In Australia, the herbicide bromoxynil (3,5-dibromo 4-hydroxy benzonitrile) is widely applied

to annual legume-based pastures, especially in subterranean clover (*T. subterraneum*) based pastures to control broadleaf weeds (Dear *et al.*, 2003). Although subterranean clover shows a moderate level of tolerance to the herbicide, it still suffers substantial forage yield depression from herbicide application. The *bxn* gene, isolated from the soil bacterium *Klebsiella ozaenae*, codes for a nitrilase enzyme, which converts bromoxynil to a relatively nontoxic product (3,5-dibromo-4-hydroxybenzoic acid) and is then further degraded by plant enzymes. As a result, the bacterial *bxn* gene was placed between the CaMV 35S promoter and NOS 3' transcription terminator. Transformation of subterranean clover tissue pieces (lower hypocotyl together with the radicle from imbibed seeds) was done by co-cultivation with *A. tumefaciens*. Selection of transformants was via spectinomycin resistance conferred by a gene from *Shigella flexneri* cloned between the CaMV 35S promoter and octopine synthase gene 3' transcription terminator from *Agrobacterium*. In field experiments and greenhouse studies, the application of bromoxynil herbicide resulted in a 50% reduction in the herbage yield of the nontransgenic control but no yield reduction was observed in transgenic subterranean clover lines (Dear *et al.*, 2003).

2.4 Disease and Pest Resistance

Serine proteinase inhibitors have been shown to retard the development of feeding insect pests. Consequently, transgenic white clover plants were generated by placing an 850 bp coding region (plus 200 bp of 3' untranslated region) of the soybean (Kunitz) trypsin inhibitor (SBTI) gene between the CaMV 35S promoter and NOS 3' transcription terminator (McManus *et al.*, 2005). Transformation was done by co-cultivation of cotyledons with *A. tumefaciens* strain LBA 4404. Selection of transformant clovers was by kanamycin resistance conferred by the *nptII* gene. The protein was expressed in transgenic clover plants studied. The recombinant inhibitor protein was effective against trypsin-like activity of black field cricket (*Teleogryllus commodus*) and grass grub (*Costelytra zealandica*), but ineffective against trypsinlike activity from light brown apple

moth (*Epiphyas postvittana*) and porina (*Wiseana copularis*) (McManus *et al.*, 2005).

The white clover mosaic virus (WCIMV), a member of the Potexviurs group, is the most widespread pathogen that causes significant yield losses to white clover production worldwide. The genomic organization of WCIMV spanning an approximately 6 kb sense RNA, encodes five genes required for replication (147 kDa), cell-to-cell and systemic movement (26 kDa, 13 kDa, and 7 kDa), and the coat protein (CP). As a potential strategy to produce virus-resistant plants, transgenic approaches were employed using three of the WCIMV genes: the CP gene (Beck *et al.*, 1993), a mutated form of the 13K movement protein gene (Beck *et al.*, 1994), and the 147 kDa replicase gene (Voisey *et al.*, 2001). The WCIMV gene constructs were placed under the control of the CaMV 35S promoter and the NOS 3' or octopine synthase transcription terminators. In all cases, transformations of white clover were done by co-cultivation with *A. tumefaciens* strain LBA 4404. Kanamycin resistance conferred by the *nptII* gene was used as a selectable marker. In one of the experiments, the protein content of the WCIMV CP transgene in four white clover plants ranged from 0.0005% to 0.005% of total soluble leaf protein. Only two transgenic white clover plants expressing relatively higher levels of WCIMV CP showed some resistance to virus inoculation (Voisey *et al.*, 2001). In general, the effect of the CP transgene was associated with a time delay in the systemic spread of the virus on inoculated transgenic plants. In the second transgenic approach, 11 transgenic white clover plants expressing a mutant WCIMV 13 kDa movement protein gene were evaluated for resistance to WCIMV inoculation (Voisey *et al.*, 2001). Of these, three transgenic clover plants were found to be resistant against high levels of WCIMV, although approximately 20% of the transgenic white clover plants were found to be infected when tested for the presence of the virus 40 days post inoculation. The WCIMV resistance displayed in the three transgenic white clovers expressing the mutant 13 kDa WCIMV was stable and was inherited in F₁ progeny obtained from pair crossing of primary clover transformants with commercial clover varieties. In a similar approach, 22 transgenic white clover

plants expressing the WCIMV replicase gene were evaluated for WCIMV resistance (Voisey *et al.*, 2001). Approximately 87% of the transgenic clover plants showed resistance to WCIMV inoculation, with five transgenic white clover plants categorized as having immunity to systemic viral infection.

Alfalfa mosaic virus (AMV) can cause significant yield losses to forage legumes including white clovers. In a study from Australia, transgenic white clover plants were generated using the *CP* gene of an alfalfa mosaic alfamovirus (AMV) (Kalla *et al.*, 2001). The AMV *CP* gene was fused between the CaMV 35S promoter or *Arabidopsis* small subunit ribulose biphosphate carboxylase/oxygenase promoter and the NOS 3' transcription terminators (Kalla *et al.*, 2001). Transformation of white clover plants was by co-cultivation with *A. tumefaciens*. Five AMV-immune transgenic white clover lines and a single resistant transgenic line were identified in controlled experiments (Kalla *et al.*, 2001). After one growing season in field plots, 60% of the nontransgenic control plants were infected with the virus; whereas, all the immune transgenic white clover plants expressing AMV *CP* transgene were found to be resistant to AMV inoculation (Kalla *et al.*, 2001).

2.5 Transgenic Clovers for Industrial Applications

Clovers have primarily been used as a source of animal feed. Plants are capable of carrying out acetylation, phosphorylation, and glycosylation as well as other post-translational protein modifications required for the biological activity of many recombinant proteins. The ease of genetic transformation and large-scale cultivation make clovers attractive targets for the production of recombinant proteins and enzymes for large-scale industrial applications and to deliver oral vaccines. Improving the economic value of clovers could be achieved by developing new uses and value-added products for clovers.

Mannheimia haemolytica is the principal microorganism responsible for bovine pneumonic pasteurellosis, or shipping fever. Leukotoxin (Lkt) has been identified as an important protective antigen of *M. haemolytica*, and a fragment, Lkt50, was shown to produce toxin-neutralizing

antibodies in rabbits. A gene encoding Lkt50, fused to modified GFP5 was placed under the control of the CaMV 35S promoter and NOS 3' transcription terminator. White clover petioles were transformed by co-cultivation with *A. tumefaciens* strains, LBA 4404 and C58. Transgenic white clover plants produced detectable levels of the fusion protein, Lkt50-GFP. A leaf extract containing Lkt50-GFP from white clover was immunogenic and elicited toxin-neutralizing antibodies in experimental rabbits. The recombinant antigen was stable after drying of the transgenic clover tissue at room temperature for 4 days (Lee *et al.*, 2001), or even after oven drying of transgenic tissue at 50 °C (Lee *et al.*, 2003). The recombinant antigen was present in the dried clover after 1 year of storage at ambient temperature. Field- and greenhouse-grown transgenic clovers maintained similar levels of Lkt50-GFP expression (Lee *et al.*, 2003).

3. FUTURE ROAD MAP

3.1 Expected Products

Genetic transformation is routine for a number of clover species and traits of interest to clover producers have been demonstrated to be effective. Published reports demonstrated the stable expression and inheritance of transgenes in transgenic white clover plants (Scott *et al.*, 1996, 1998). Transgenic white clover plants had been outcrossed to cultivar material as a first step toward the breeding and field release of virus-resistant white clover cultivar (Woodfield and White, 1996; Voisey *et al.*, 2001). Breeding strategies for developing transgenic white clover cultivars have been suggested (Woodfield and White, 1996). However, the current highly segmented clover seed production industry and high cost of commercialization of biotechnology traits does not favor the commercialization of transgenic clover in the near future.

3.2 Risks and Concerns

White clover has many of the characteristics of a successful weed and transgenic forms may be considered to be environmental threats in some jurisdictions. A risk assessment carried

out in Australia (Australian Government, 2004) showed that there was a potential risk of weediness, especially in disturbed sites. However, the chances of white clover transferring genes to other organisms were found to be negligible as it does not naturally hybridize with any other species.

1. INTRODUCTION

1.1 History, Origin, and Distribution

Apple (*Malus × domestica* Borkh.) is the most important temperate tree fruit crop grown in North America and around the world, and belongs to the family Rosaceae and subfamily Pomoideae. It has been reported that the domestic apple arose some 8–12 million years ago in refuge fruit forests in Central Asia, primarily in the Tien Shan region, an area extending from the current region of Kazakhstan, through the Xinjiang Province in China, and all the way west to Uzbekistan (Juniper *et al.*, 1999). Through natural distribution, selection, random hybridization, as well as adaptation over millions of years, the new apple of the Tien Shan, *Malus sieversii* Lebed., having fruit ranging in size from small (2 cm) to large (6 cm), has played a major role in the origin of the cultivated apple. It is likely, that to the east of this region, *M. sieversii* could have hybridized with *Malus prunifolia* (Willd.) Borkh., *Malus baccata* (L.) Borkh., and *Malus sieboldii* (Reg.) Rehd. and to the west with *Malus turkmenorum* Juz., *Malus orientalis* L., and *Malus sylvestris* (L.) Mill. (Juniper *et al.*, 1999). Recent studies utilizing molecular

markers, random amplified polymorphic DNAs (RAPDs), along with phylogenetic tree analysis have confirmed that *M. sieversii* is the primary progenitor of the cultivated apple, *M. × domestica* (Lamboy *et al.*, 1996; Zhou and Li, 2000).

Cultivation of the apple has taken place since the age of the ancient Greeks and the Romans, who following their travels and invasions, spread these practices throughout Europe and Asia (Janick *et al.*, 1996; Juniper *et al.*, 1999). Cultivars were selected and propagated ever since, particularly as vegetative propagation, via grafting, was practiced over 2000 years ago. As cultivars were brought into Europe, particularly those making it to the British Isles, they hybridized among themselves, and underwent spontaneous mutations resulting in new cultivars. Later, apples were brought over to North America, and cultivation practices of the colonial Europeans were further adapted and modified. As pioneers of distribution of apple seed throughout North America, such as John “Johnny Appleseed” Chapman (1774–1825), random hybridizations took place that eventually led to the discovery of chance seedlings that became significant apple cultivars, such as “Delicious”, “Golden Delicious”, and “Jonathan” that were adapted for worldwide growing conditions (Juniper *et al.*, 1999).

1.2 Botanical Description

The genus *Malus* has from 25 to 33 species depending on taxonomic treatment, along with several subspecies, arranged into three geographical groups (Chinese, European, and American) and five botanical sections (Janick *et al.*, 1996; Juniper *et al.*, 1999). The genus *Malus* is characterized by fruits consisting of two to five carpels enclosed by a fleshy tissue.

Malus species as well as clones within the same species have varying ploidy levels as these are more than likely collected from different trees and/or different locations (Schuster and Büttner, 1995; Tatum *et al.*, 2005). Botanical varieties and/or genotypes of few other *Malus* species, such as *M. halliana* and *M. hupehensis*, also show varying ploidy levels as well (Schuster and Büttner, 1995). It has been suggested that differences in ploidy levels in the same species is likely attributed to frequent hybridizations within the genus *Malus*. The cultivated apple has a complex genome consisting of 34 chromosomes per diploid genome. The origin of the basic haploid number of $n = 17$ in *Malus* and other *Pomoideae* has been attributed to hybridization between two remote ancestral types, *Prunoideae* ($n = 8$) and *Spiroideae* ($n = 9$) (Derman, 1949; Challice and Westwood, 1973). On the other hand, Darlington and Moffett (1930) have suggested that the basic number $n = 7$ (very common in other genera of *Rosaceae*) was doubled with three of the chromosomes repeated a third time leading to the haploid number of $n = 17$. DNA flow cytometric analysis has indicated that the mean of diploid genotypes investigated has a DNA content of 1.582 pg/2C, and therefore a single chromosome accounts for 0.045 pg (picogram) (Tatum *et al.*, 2005). Given a 0.23 pg variation among diploids, this suggests that nuclear DNA content variation among diploid apple cultivars and species may equal to the DNA amount of almost six chromosomes. Given the complexity of the apple genome and its suggested allopolyploid origin (Schuster and Büttner, 1995; Evans and Campbell, 2002; Tatum *et al.*, 2005), the apple can easily withstand the loss of a certain amount of DNA, and there is a slight tendency toward diminished haploid nuclear DNA content with increased polyploidy (Tatum *et al.*, 2005).

Apple has gametophytic self-incompatibility, and it is controlled by a single multiallelic *S* locus.

The *S* locus has *S2-* (= *Sa-*), *S3-*, *S5-*, *S7-* (= *Sd-*), *S9-* (= *Sc-*), *Sf-*, *Sg-*, *S24-* (= *Sh*), *S26-*, and *S 27-* alleles (Matsumoto and Kitahara, 2000), and these encode RNase linked to *S*-locus (*S*-RNases), many of which have been cloned (Broothaerts *et al.*, 1995). Therefore, when the pollen *S*-allele matches one of the pistil's *S*-alleles, fertilization is inhibited. Several of these alleles of the *S* locus in apple have been identified and their nucleotide sequences have been determined (Broothaerts, 2003). Based on the diversity of nucleotide sequences encoding the *S*-RNase family members, allele-specific polymerase chain reaction (PCR) primers have been developed to selectively amplify and identify particular *S*-alleles, and later this approach has been modified in order to identify additional alleles (Janssens *et al.*, 1995; Broothaerts, 2003). The new numbering introduced *S*₁₆, *S*₁₉, *S*₂₂, and *S*₂₃. Recently, Broothaerts *et al.* (2004b, b) have been able to identify 18 different *S*-alleles, and these have been used to determine *S*-genotypes of 150 diploid and triploid European, American, and Japanese apple cultivars. This has indicated that three *S*-alleles (*S*₂, *S*₃, and *S*₉) are very common in these cultivars, probably attributed to the widespread use of the same breeding parents, and seven alleles are very rare (*S*₄, *S*₆, *S*₈, *S*₁₆, *S*₂₂, *S*₂₃, and *S*₂₆).

1.3 Economic Importance

World apple production is around 42 million metric tons (based on 2004/2005 data), and this is valued at US\$1.5 billion (United States Department of Agriculture (USDA) Agricultural Attache Reports and the US National Agricultural Statistics Service.). China is the leading producer of apples, followed by United States, Turkey, Poland, and Italy. The US apple crop is at 4.6 million metric tons (2004/2005 data). The southern hemisphere has increased production of apples to around 4.4 million metric tons, with Argentina and Chile leading the way. World production of apple juice is around 1.26 million metric tons (USDA-ARS), of which 1.19 million tons are exported. China exports almost 50% of this world total. The United States is one of the world's largest importers of apple juice concentrate. Although global apple consumption has been either stagnant or on the decline, consumption of fresh apples in developed

countries has been on the rise with improved choices and availability of new cultivars. China is the largest consumer of apples, followed by the United States, Turkey, Germany, and Italy.

There are over 7500 cultivars of apples grown in the world. In the United States, over 100 cultivars of apples are grown commercially. Although apples are grown in all the 50 US states, they are commercially grown in only 36 states. In 2002, US consumers ate an average of 42.2 pounds of fresh apples and processed apple products, of which 62% was consumed as fresh fruit.

Apple fruits are characterized as healthful fruits as they do not contribute any fat, sodium, or cholesterol to the human diet. A medium apple contains about 80 calories. Apple fruits are great sources of fiber and pectin, with an average fruit containing five grams of fiber. Apple fruits are rich in sugar and starch. Unripe apples contain as much as 15% starch, while ripe apples contain 8–14% sugar (Reed, 1975). As the size of young fruitlets reach 20 mm in diameter, starch begins to rapidly accumulate (Magein and Leurquin, 2000). As fruit begins to ripen, starch stored in the flesh gradually converts into sugar. Levels of starch and sugar accumulation in apple fruits are genotype dependent. For example, the “Fuji” apple cultivar is a low-starch apple; while “Granny Smith” is a high-starch apple. Next to “Granny Smith”, “Pink Lady” is the second highest starch-accumulating apple grown commercially. Fruit starch content has a strong influence on both eating and processing qualities of apple, as starch together with organic acids are known to greatly contribute to flavor composition. Apples with low starch content combined with low levels of organic acids taste sweet, while those rich in both starch and acid are rather tart. Meanwhile, starch is generally considered to be a problem for processing of apple juice (Carrin *et al.*, 2004). High starch content will contribute to prolonged filtration and result in post processing cloudiness of the apple juice. In order to degrade and eliminate insoluble starch, amylases are widely used during the processing of apple juice production.

1.4 Traditional Breeding

Apple breeding for both fruiting cultivars and rootstocks has evolved over hundreds of years

from accidental and random observations of chance seedlings and spontaneous mutations with desirable fruit and tree characters to deliberate and careful evaluations of populations derived from either open-pollinated seedlings, controlled crosses, or induced mutations. Those individuals exhibiting outstanding or unique fruit characters such as fruit color, pigmentation patterns, acidity and sugar content, juiciness, firmness, as well as various alkaloids and flavor components were the first to be selected. Interest in manipulating and controlling tree growth and stature has led to the identification and selection of desirable rootstocks with dwarfing ability that influences the overall size of the grafted tree, anchorage, as well as resistance to various diseases and pests (Korban and Chen, 1992; Janick *et al.*, 1996).

Over time, breeding objectives continued to incorporate all of the above-mentioned desirable traits, as well as expand to other traits, for both scion cultivars and rootstocks. However, as controlled sexual hybridizations among selected parents became more widely practiced, and breeding programs began to expand and grow, emphasis was placed on selecting parents with desirable fruit characters. Large populations of seedlings were then planted with the anticipated hope of identifying outstanding selections. As the generation cycle of apple breeding can be anywhere from 5 to 7 years, progress was slow. As the genetic control mechanisms of various reproductive and vegetative traits were investigated and became known, breeding efforts made more progress when traits were known to be controlled by qualitative rather than quantitative genes. Approximately, 30 traits or so are known to be controlled by either one or two major genes, and the majority of these traits are primarily associated with either disease and/or insect resistance (Janick *et al.*, 1996). However, most traits, particularly those associated with fruiting and fruit quality, are polygenically controlled.

Over the years, apple breeding programs from all over the world, especially those in New Zealand, Japan, and the United States, have been successful in developing new apple cultivars that have made significant impact on the commercial market. Such cultivars as “Gala”, “Empire”, “Fuji”, “Pink Lady”, “Jonagold”, and “Braeburn”, among others, have become important commercial cultivars worldwide. These cultivars are selections from

F₁ populations derived from controlled crosses between outstanding cultivars used as parents. These cultivars were selected mainly for fruit quality traits, and all these traits are controlled by polygenes. Although most of these apple cultivars are diploids, there are triploid cultivars as well, such as “Jonagold” and “Crispin” (also known as “Mutsu”).

Successful breeding efforts for traits controlled by polygenes can be best exemplified by those cultivars and rootstocks with enhanced tolerance to cold temperatures. Cultivars such as “Honeycrisp” from the Minnesota breeding program and rootstocks such as the Budagovsky series from Russia and the P-series from Poland are also making an impact on the commercial market.

Breeding programs have also been successful in enhancing disease resistance in apple. The best such example is the development of new cultivars with resistance to the fungal disease, apple scab, caused by *Venturia inaequalis* (Cke.) Wint. Having identified single major genes for resistance to apple scab in small-fruited crabapple *Malus* species, the Purdue-Rutgers-Illinois (PRI) cooperative breeding program and later the Cornell breeding program have been able to develop more than 20 apple cultivars with resistance to apple scab. These cultivars resulted from selections following 4–6 generations of controlled crosses using the whole pool of scab-resistant cultivars as “recurrent” parents in crosses (30–40 years). These successful efforts were also replicated in various international breeding programs such as those found in Canada, France, Brazil, England, Australia, Czech Republic, Germany, Romania, and Hungary, among others, in developing many other well-adapted new cultivars with resistance to apple scab. However, these cultivars are yet to have a significant impact on the commercial market, although there is hope that newly released cultivars, such as “GoldRush”, “Juliet”, and “Ariane” may do so in the future.

An example of successful breeding for pest resistance is the development of rootstocks resistant to woolly apple aphid, *Eriosoma lanigerum* Hausm., by incorporating the *Er* gene for resistance, derived from “Northern Spy”, into the Malling rootstock breeding programs in the United Kingdom. The resulting woolly apple aphid-resistant F₁ selections, such as MM106 and MM111, have become commercially important

rootstocks that are grown worldwide. They are now being superseded by rootstocks from the Geneva, NY breeding program that incorporate resistance to fire blight as well as to woody apple aphid.

So far, all apple breeding efforts involve *in vivo* screening of either whole seedlings or detached plant tissues for disease resistance, insect resistance, cold hardiness, dwarf compact habit, or any combinations of these traits. Moreover, this is often followed by *in vivo* screening of whole trees for flowering, fruiting, fruit quality, and tree characters. In recent years, molecular mapping studies of the apple have been underway with over 1000 markers, including isozymes, RAPDs, restriction fragment length polymorphisms (RFLPs), amplified fragment length polymorphisms (AFLPs), simple sequence repeats (SSRs), and expressed sequenced tag-SSRs (EST-SSRs) mapped to 17 linkage groups (Xu and Korban, 2000; Liebhard *et al.*, 2002, 2003; Gardiner *et al.*, 2003, 2007; Naik *et al.*, 2006; Silfverberg-Dilworth *et al.*, 2006). These molecular markers have not yet been used in marker-assisted selection although some promising efforts are underway (Bus *et al.*, 2000; Huaracha *et al.*, 2004; Gardiner *et al.*, 2007), and these will aid in expediting early screening of seedlings for various traits, particularly for flowering and fruiting characters.

1.5 Limitations of Conventional Breeding and Rationale for Transformation Breeding

As mentioned above, conventional breeding efforts for improvement of the apple have yielded substantial success in the development of several of cultivars that have been successfully introduced to the commercial industry. However, these breeding efforts have incurred major commitments of time, money, and land space, as well as personnel. As the apple is highly heterozygous, self-incompatible, and has a generation cycle of 5–7 years, the progress made thus far via traditional breeding has been rather modest when compared to other fruit crops, such as peach and table grape, and less so, when compared to herbaceous horticultural crops, such as tomato and beans. As a result of the slow progress made so far, the number

of apple breeding programs worldwide decreased for several years, and has now recovered. In the meantime, research efforts have moved toward identifying molecular markers linked to traits of interests, as mentioned above, developing genetic linkage maps, as well as isolating and cloning genes controlling various desirable traits, including those controlling juvenility, flowering, fruit quality, and disease resistance.

For example, Kotoda *et al.* (2006) isolated and cloned *MdTFL1* (*M. × domestica TFL1*), a gene involved in the maintenance of the juvenile and vegetative phase in apple. However, to confirm the functionality of *MdTFL1*, this gene was introduced into apple, in an antisense orientation, via *Agrobacterium*-mediated transformation, and among recovered transgenic lines, one line was identified that flowered after 8 months following transfer to the greenhouse, while nontransformed control plants had flowered after nearly 6 years. However, flowering after 8 months in the greenhouse has been shown with normal apple seedling (Aldwinckle, 1975). It is important to add that flower organs of trees of this transgenic line were normal in appearance and capable of setting and producing fruit. Interestingly, some flowers of these transgenic apples developed without undergoing dormancy. Therefore, this study suggested that expression of *MdTFL1* gene in apple might influence flower development as well as flower induction. Apple orthologs of several genes controlling juvenility and flowering time, such as *AFL1*, *AFL2*, and *MdAPI* (*MdMADS5*), have also been isolated and characterized (Kotoda *et al.*, 2000, 2002; Kotoda and Wada, 2005). In another example, the *Vf* gene(s) of apple scab resistance was cloned and characterized (Vinatzer *et al.*, 2001; Xu and Korban, 2002), and when two of the four *Vf* paralogs, found clustered within the *Vf* locus, were introduced into scab-susceptible apple cultivars via *Agrobacterium*-mediated transformation, enhanced resistance to apple scab was observed in some transgenic apple lines (Malnoy *et al.*, 2007e).

Various other genes from apple have been cloned and characterized in recent years as well. For example, Gao *et al.* (2005) isolated and characterized two sorbitol transporter genes, *MdSOT1* and *MdSOT2*. Comparisons of expression of transporter genes, especially in various sink tissues including watercored and nonwatercored

fruit tissues indicated that sorbitol transporter expression was evident in all sink tissues tested with the exception of watercore-affected fruit tissues. Therefore, expression of these genes in apple fruit would likely overcome problems of watercore in apple fruit.

In recent years, genomics resources for apple have become available, such as the construction of bacterial artificial chromosome (BAC) libraries (Paton *et al.*, 1999; Xu *et al.*, 2001, 2002) and generation of over 300 000 ESTs (Korban *et al.*, 2005; Newcomb *et al.*, 2006), our capabilities for isolating and cloning of genes controlling various economically important vegetative and reproductive traits have significantly increased. Therefore, efforts to improve the apple via the tools of genetic engineering, and thereby bypassing the lengthy strategies used in traditional breeding have become more critical, and much needed.

2. DEVELOPMENT OF TRANSGENIC APPLES

2.1 Apple Transformation Procedure

Development of an effective system for gene transfer in apple depends largely on the availability of tissue culture techniques that permit efficient DNA delivery, regeneration of shoots, selection of transformants, and propagation of transgenic plants. Increasing leaf regeneration efficiency is critical for the development of a transformation system in apple using an *Agrobacterium tumefaciens* vector (Klee and Rogers, 1989) or by a biolistic process. In many instances, the lack of efficient regeneration systems is the major limiting factor preventing the development of gene transfer technologies for perennial crops (Dandekar, 1992).

The first report of *in vitro* regeneration of adventitious shoots from apple was made by Liu *et al.* (1983a, b) using apple seedlings. Several later reports (Barbieri and Morini, 1987; Welandar, 1988; Fasolo *et al.*, 1989; Sriskandarajah *et al.*, 1990; Swartz *et al.*, 1990; Korban *et al.*, 1992; James *et al.*, 1994) revealed critical factors affecting the frequency of leaf regeneration in apple scion cultivars, rootstocks, and seed explants. They include nitrogen source and concentration, growth regulators, incubation conditions, leaf origin, leaf

maturity and position on the stem, mode of excision, and explant orientation.

Greensleeves was the first apple cultivar to be transformed (James *et al.*, 1989) with an efficiency of transformation between 0.1% and 0.5% on a per explant basis. The method used was based on a leaf disk transformation method using disarmed strains of *A. tumefaciens*. The *GUS* gene in the transformed Greensleeves plant produced in this way displayed stable patterns of expression in fruit and Mendelian segregation in the progeny (James *et al.*, 1995, 1996). To date, variations of this method have been used to transform different *M. × domestica* cultivars (30) and rootstocks (7), *M. prunifolia* (2), and one *M. robusta* variety (Table 1).

The techniques of transformation used for these different apple genotypes are quite similar (Table 1). Due to the fact that all genotypes do not respond similarly to the same procedure of transformation some modifications have been reported.

2.1.1 Nature of the explants

In a large majority of the procedures published, young expanded apple leaves were used as explants. The regeneration of transgenic lines from leaves has been enhanced by placing the leaf segment abaxial side up on the medium, possibly due to increased oxygen exchange since stomata are located abaxially (Yepes and Aldwinckle, 1994). Sriskandarajah and Goodwin (1998) reported that conditioning of apple shoots for several days in an appropriate liquid medium enhances the regenerative capacity of leaf explants by reducing the need for an extended callus phase. However, this conditioning process for explants has not been subsequently reported in transformation protocols. Other procedures reported use of internodal (Liu *et al.*, 1998, 2001), shoot (Pawlicki-Jullian *et al.*, 2002), and stem explants (Yamashita *et al.*, 2004), and protoplast (Ratnasiri *et al.*, 2002; Hyung *et al.*, 1995). The regeneration of plants from protoplasts is a lengthy process compared with standard tissue transformation. Therefore, the transformation of protoplasts is unlikely to be a source of new transgenic plant material, but the system would be useful as a high-throughput approach for transient assay of gene function or protein targeting.

2.1.2 Inoculation procedures

Two inoculation procedures have been used. The first consists of wounding the leaves with a scalpel soaked in the inoculum (Wilson and James, 2003). The second is to bathe prewounded leaves in the inoculum for a few minutes (De Bondt *et al.*, 1994; Norelli *et al.*, 1994) to several hours (Mooney and Goodwin, 1989). Other modes of inoculation have been tested but did not significantly increase the rate of transformation. For example, sonication of the leaf explants in presence of the inoculum has been reported to increase transformation of the apple cultivar Holsteiner but not of Elstar (Szankowski *et al.*, 2001). Vacuum infiltration of Royal Gala leaves was reported to have no effect on transformation (Norelli *et al.*, 1996).

2.1.3 Strains of agrobacterium used

About 95% of apple transformation procedures were based on use of *A. tumefaciens*, with the remaining 5% using *Agrobacterium rhizogenes* for the transfer DNA (T-DNA) integration (Pawlicki-Jullian *et al.*, 2002; Yamashita *et al.*, 2004). The efficiency of transformation depended on the apple cultivars and the strain of *A. tumefaciens* used. For example, the Jork 9 rootstock was transformed at 8.3% efficiency with the strain EHA105 and 1.5–7.2% efficiency with the strain C58C1 (Zhu *et al.*, 2001b).

2.1.4 The selectable marker used

In most cases (90%), kanamycin has been used as a selectable marker. Concentration of kanamycin used for the regeneration of transgenic apple varied depending on the cultivar. Two other antibiotics have been used as selectable agents: hygromycin (Dolgov *et al.*, 2000, 2004a) and phosphonothricin (Szankowski *et al.*, 2003).

2.1.5 Other modifications

Other modifications have been made to these procedures to increase their transformation efficiency. These modifications included the use of plant phenolic compounds (acetosyringone,

<i>Malus robusta</i> Rehd. Balenghaitang	Leaf	Leaf cut in three pieces and soaked in inoculum for 5 min	LBA4404	BA, NAA	MS with sucrose	<i>LeIRT2</i>	Kanamycin 50 mg l ⁻¹	1.2%	Qu <i>et al.</i> , 2005

betain phosphate) to increase the expression of several virulence genes in *A. tumefaciens*, and the gelling agent, growth regulator (Table 1), source of carbon (sucrose or sorbitol), nitrogen source, and concentration of AgNO₃ (Seong *et al.*, 2005), binary vector, and antibiotics (cefotaxin, cefoxitin, carboxillin) used. Antibiotics prevent and eliminate contamination by surviving *Agrobacterium* that could occur after the transformation procedure. Hammerschlag *et al.* (2000) reported the generation of *Agrobacterium*-free transgenic apple by vacuum infiltration of explants inoculated with *Agrobacterium* with an acidified medium with a high concentration of antibiotics (500 mg l⁻¹ carbenicillin, cefotaxime, and cefoxitin). Another way to avoid contamination with *Agrobacterium* is to bathe prewounded leaves in the inoculum for a short time.

All these apple transformation procedures allowed regeneration of transgenic apple lines with an efficiency of 0.02–9% with the exception of the procedure described by Norelli *et al.* (1994, 1996), which had an efficiency of 5–50% for the cultivars M.26, McIntosh, and Galaxy. After improvements in their procedures, the rate of transformation for Galaxy and M.26 can be as great as 50% and 80%, respectively (H.C. Aldwinckle, personal communication).

2.2 Traits Improved

2.2.1 Control of transgene expression

The genetic construct integrated into the apple genome to control the expression of the gene of interest must contain a DNA sequence encoding the active protein and several regulatory sequences. These sequences control when, how, and where the protein of interest will be expressed in the plant. Among these regulatory sequences, the promoter identifies the coding region and allows messenger RNA (mRNA) transcription, and also determines when, and in some cases, under what conditions transcription should be initiated. The CaMV 35S promoter from cauliflower mosaic virus (CaMV) has been used widely in transgenic plants. In apple it controls 60% of transgenes integrated in the apple genome because it provides continuous expression regardless of developmental stage in most plant tissues (constitutive expression)

(Table 2). Duplication of the upstream (5') DNA sequences of the 35S promoter results in elevated levels of transcription (Kay *et al.*, 1987). With such a promoter, a gene is expressed in the majority of tissues during most phases of plant growth and development. This limited temporal and spatial regulation may be suitable for proof of concept experiments, but presents a number of potential drawbacks for use in genetically improved crops. For example, the presence of transgenes driven by constitutive promoters may result in homology-dependent gene silencing, particularly when the promoter is also highly active (Vaucheret *et al.*, 1998). Thus, gene expression under the control of inducible promoters (tissue, developmental stage, and pathogen specific) is preferred in any strategy to produce transgenic plants with transgene-mediated improvements in resistance to pathogens. This targeted gene expression could be advantageous in providing resistance where and when needed, limiting the amount of transgenic protein in fruit, reducing the plant energy cost for transgenic protein synthesis, and reducing unnecessary exposure of nontarget organisms to the protein (Norelli and Aldwinckle, 2000).

Knowledge of genes involved in plant pathogen interactions, flowering time, and metabolic pathways are still limited in apple and no homologous apple promoters are able to drive high levels of gene expression, specifically in response to pathogens or the function considered. Only two functional apple promoters have been reported and studied, the scab-resistance promoters (Silfverberg-Dilworth *et al.*, 2005a) and the PR10 promoter (Puhlinger *et al.*, 2000). Therefore, different inducible promoters isolated from tobacco, potato, *Brassica napus*, *Vitis vinifera*, soybean, *A. rhizogenes*, and virus have been used in apple to control the expression of transgenes (Table 2). The responses of some of these promoters to different stresses (pathogen or chemical) have been studied. Their activity differs in different plant organs (Table 2).

The potato promoter *gstI* that encodes a glutathione S transferase was studied for its ability to respond to *Erwinia amylovora*. This promoter mediated rapid and local transcriptional activation in potato in response to fungal and viral pathogens. Transcription from this promoter is not induced by environmental abiotic stimuli, such as wounding or heat shock (Martini *et al.*, 1993; Strittmatter *et al.*, 1996). The ability of the *gstI* promoter

Table 2 Traits expressed in transformed apple cultivars

Trait	Apple cultivars	Gene introduced	Gene origin	Promoter	Principal results	References
Bacterial resistance <i>Agrobacterium tumefaciens</i> (crown gall) <i>Erwinia amylovora</i> (fire blight)	Jonagold	<i>iaaM</i> and <i>ipt</i> (silencing)	<i>A. tumefaciens</i>	CaMV 35S FMV	Silencing of <i>iaaM</i> gene expression was observed. Reduction and abolition of Crown Gall formation was observed.	Viss <i>et al.</i> , 2003
	Gala	SB37 (+/-sp) Shiva 1 (-sp)	Synthetic peptide	Pin2 CaMV 35S	Some SB-37 transgenic lines with partial resistance in the orchard	Norelli <i>et al.</i> , 1999; Aldwinckle <i>et al.</i> , 2003a
	Royal Gala	MB39 (+sp)	Modified cecropin	Osmotin (wound inducible)	Three of seven transgenic lines showed an increase in resistance in greenhouse (2.5–3.3 fold more resistance than the control)	Liu <i>et al.</i> , 2001
	Royal Gala	MB39 (+sp)	Modified cecropin	Osmotin (wound inducible)	Three of seven transgenic lines showed an increase in resistance in greenhouse (2.5–3.3 fold more resistance than the control)	Liu <i>et al.</i> , 2001
	M.26	<i>Attacin E</i>	<i>Hyalophora cecropia</i> (giant silk moth)	Pin2 CaMV 35S	Some transgenic lines showed partial resistance in greenhouse and in the orchard. Increased resistance when signal peptide and translation enhancer (AMV) were used	Norelli <i>et al.</i> , 1994; Ko <i>et al.</i> , 2000; Aldwinckle <i>et al.</i> , 1998, 2003a
	Pinova, Pilot, Pirol, Pingo, Elstar, Remo, Liberty, Reka, Pi-AU 56-83 Gala	Attacin E (-sp) T4 Lysozyme	<i>Hyalophora cecropia</i> (giant silk moth) <i>T4 Bacteriophage</i>	Pin2 CaMV 35S	Some transgenic lines showed partial resistance in greenhouse	Hanke <i>et al.</i> , 2000
		T4 Lysozyme alone or associated with attacin E	<i>T4 Bacteriophage Hyalophora cecropia</i>	Pin2 (attacin E) CaMV 35S (T4ly)	Some transgenic lines showed partial resistance in greenhouse. No increase of resistance when this gene was combined with attacin gene	Ko <i>et al.</i> , 1998, 2002; Aldwinckle <i>et al.</i> , 1998, 2003a

Pinova	<i>Dpo</i>	Phage ϕ Ea1h	CaMV 35S	Sixty-one out of 83 transgenic lines appeared significantly less susceptible than parental parent Pinova after inoculation of detached leaves <i>in vitro</i> . Three lines appeared less susceptible after inoculation in greenhouse.	Hanke <i>et al.</i> , 2003
M.26			CaMV 35S Gst1	Increased of resistance to fire blight. Higher resistance observed when the <i>Dpo</i> gene was driven by CaMV 35S promoter.	Borejsza-Wysocka <i>et al.</i> , 2007
M.26	<i>HrpN</i>	<i>Erwinia amylovora</i>	Gst1 (wound inducible)	Most of the transgenic lines had partial resistance to <i>E. amylovora</i> in greenhouse and in the field. Two of these lines showed a level of resistance similar to the resistant rootstock M.7.	Abdul-Kader <i>et al.</i> , 1999; Aldwinckle <i>et al.</i> , 2003a; Malnoy <i>et al.</i> (submitted)
Galaxy M.26	<i>MpNPR1</i>	Apple	Pin2 CaMV 35S	Significant reduction in susceptibility to <i>E. amylovora</i> of 33–86% for Galaxy; M.26 showed a less substantial reduction in susceptibility compared to Galaxy (0–70%).	Malnoy <i>et al.</i> , 2004, 2007e
Galaxy	<i>DIPM</i> (silencing) 4 different genes	Apple	CaMV 35S	Some transgenic lines showed silencing of the DIPM genes and an increase in resistance to <i>Erwinia amylovora</i> .	Borejsza-Wysocka <i>et al.</i> , 2006
Royal Gala	<i>Avidin Streptavidin</i>	Nd	CaMV 35S	High level of resistance to larvae of lightbrown apple moth (<i>Epiphyas postvittana</i>). Mortality of the larvae was between 80% and 90% in the transgenic lines compare to 14% in the untransformed apple.	Markwick <i>et al.</i> , 2003

Fungal resistance						
Fungal resistance	Melba	<i>Thaumatin</i>	<i>Thaumatooccus danielli</i> (Plant)	CaMV 35S	Nd	Dolgov <i>et al.</i> , 2004
<i>Alternaria mali</i>	McIntosh	<i>Rab</i>	Plant nd	Wound-inducible promoter	Smaller disease lesion and spot size in transgenic lines compared to untransformed	Kim <i>et al.</i> , 2007
<i>Venturia inaequalis</i> (apple scab)	McIntosh	<i>Endochitinase</i> (<i>ech42</i>) <i>Exochitinase</i> (<i>nag70</i>)	Trichoderma atroviride (fungus)	2CaMV 35S	Negative correlation between growth of transgenic lines and endochitinase activity was observed Six of eight transgenic lines expressing endochitinase were more resistant than control. Disease severity was reduced by 0–99.7% (number lesion) and 0–90% (% of leaf area infected) Exochitinase was less effective than endochitinase Some plants expressing both genes were more resistant than plants expressing either single gene	Bolar <i>et al.</i> , 2000, 2001
	Ariane Galaxy	<i>Endochitinase</i> (<i>ech42</i>) <i>Exochitinase</i> (<i>nag70</i>)	Trichoderma atroviride	2CaMV 35S	Negative correlation between growth of transgenic lines and endochitinase activity was observed Reduced of growth appeared to be associated with high lignin content, peroxidase, and glucanase activity All the lines with high endochitinase activity exhibited significant reduction of scab symptoms	Faize <i>et al.</i> , 2003
	Jonagold	<i>Ace-AMPI</i> <i>Rs-AFP2</i>	Onion Radish	CaMV 35S	<i>Rs-AFP2</i> expressing shoot showed eightfold to 32-fold antifungal activity compared to the control <i>Ace-AMPI</i> expressing shoot showed fourfold increased antifungal activity relative to control plants	De Bondt <i>et al.</i> , 1999

Gala Elstar Ariane Galaxy	<i>Ai-AMP</i> <i>Hordothionin</i>	Nd Barley	CaMV 35S CaMV 35S	Nd Decrease in scab symptom development	Broothaerts <i>et al.</i> , 2000 Janse <i>et al.</i> , 2002
	<i>Puroindoline-b</i>	Wheat	CaMV 35S	Reduction of symptoms in transgenic Galaxy (55% for best lines) and in Ariane (64%) after inoculation with the apple scab race 6 No increase in resistance was observed in the transgenic Galaxy lines after inoculation with the apple scab race 1 Hervf2 confers scab resistance to the susceptible apple cultivar Gala Acquired resistance is race specific	Faize <i>et al.</i> , 2004
Gala	<i>HcrVf2</i>	Apple	CaMV 35S	Transgenic lines expressing either <i>Vf1</i> or <i>Vf2</i> showed a significant increase in resistance to <i>Venturia inaequalis</i> Transgenic lines expressing <i>Vf4</i> gene were as, or more susceptible than control	Barbieri <i>et al.</i> , 2003; Belfanti <i>et al.</i> , 2004; Silverberg-Dilworth <i>et al.</i> , 2005a Malnoy <i>et al.</i> , 2007d
Galaxy McIntosh	<i>Vf1</i> , <i>Vf2</i> and <i>Vf4</i>	Apple	Their own native promoter		
Environmental stress resistance					
High and low temperature stress	Royal Gala	Pea	Nd	Transgenic lines showed different degrees of increased resistance to high and low temperature stress Resistance to freezing injury was 1–3° greater and up to 7° increase to acute heat stress Two of 9 transgenic lines were tested for their iron deficiency tolerance One of these two lines showed a higher resistance to iron deficiency (21–34% greater than control)	Artlip <i>et al.</i> , 2006
Iron deficiency tolerance	Balenghaitang Malus robusta	Tomato	CaMV 35S		Qu <i>et al.</i> , 2005

Modified metabolism Production of the phytoalexin resveratrol	Elstar Holsteimer cox	<i>Stilbene synthase</i>	<i>Vitis vinifera</i>	Stilbene promoter (UV, wound and pathogen inducible)	Transgenic lines produced a resveratrol glucoside (piceid) that is accumulated in the plant, skin, and flesh of the fruit. Accumulation of piceid after induction by UV treatment does not affect the accumulation of other compounds of the flavonoid and phenylpropanoid pathway Expression of the stilbene synthase gene does not affect the leaf shape, flower morphology or color, or fruit shape and size compared to control plants and fruit	Szankowski <i>et al.</i> , 2003; Ruhmann <i>et al.</i> , 2006
Decreased flesh browning	Orin Fuji	<i>Polyphenol oxidase antisense</i>	Apple	CaMV 35S	Transgenic lines, in which PPO expression is reduced, had less flesh browning	Murata <i>et al.</i> , 2000, 2001
Sugar accumulation	Orin	<i>Sorbitol 6 phosphate dehydrogenase (S6PDH)</i>	Apple	CaMV 35S	Transgenic lines showed different expression level of S6PDH Lines with less activity contained only a low level of sorbitol but showed sixfold to sevenfold increase in sucrose. The growth of this plant stopped early during the summer due a deficiency of sugar	Kanamaru <i>et al.</i> , 2004
	Greensleeves	<i>Aldose 6 phosphate (A6PR) antisense</i> also called <i>S6PDH</i>	Apple	CaMV 35S	Lines with increased amount of S6PDH activity had increased sorbitol and sucrose content Antisense inhibition of A6PR expression significantly decreased A6PR activity and sorbitol synthesis, but increased concentration of sucrose and starch at both dusk and predawn Silencing leaf sorbitol synthesis alters long-distance partitioning and apple fruit quality	Cheng <i>et al.</i> , 2005; Zhou <i>et al.</i> , 2006; Teo <i>et al.</i> , 2006

Down-regulation of ethylene production	Royal Gala	<i>Aminocyclopropane 1 carboxylic (ACC) synthase 2 antisense</i>	Apple	CaMV 35S	Production of apple tree with down regulation of ethylene production. Some lines had fruits with delayed softening.	Hrazdina <i>et al.</i> , 2003
	Greensleeves	<i>ACC synthase antisense ACC oxidase antisense</i>	Apple	CaMV 35S	Some transgenics were significantly suppressed in ethylene production The fruit of these apple trees was firmer and displayed increased shelf life No difference was observed in sugar or acid accumulation in these fruit compared to the control. However, a significant and dramatic suppression of the synthesis of volatile esters was observed	Dandekar <i>et al.</i> , 2004; Defilippi <i>et al.</i> , 2004, 2005a, 2005b
Cell adhesion	Royal Gala	<i>Polygalacturonase</i>	Apple	CaMV 35S	Phenotypic modification of apple tree (silvery colored leaves and leaf shedding) Mature leaves with malfunctioning and malformed stomata	Atkinson <i>et al.</i> , 2002
Apple allergen	Elstar	<i>Mal dl Rnai</i>	Apple	CaMV 35S	Reduction of <i>Mal dl</i> expression in the transgenic silenced apple. This translated into significantly reduced <i>in vivo</i> allergenicity	Glissen <i>et al.</i> , 2005

Trait	Apple cultivars	Gene introduced	Gene origin	Promoter	Principal results	References
<i>Promoter</i> Gene expressed in restricted area	Greensleeves		<i>Tomato soybean</i>	Rubisco small subunit (SSU) promoter CaMV 35S	SSU promoters are active in the photosynthetically active leaf mesophyll and palisade cells. The mean activity of the two SSU promoters in apple leaves appeared to be approximately half that of the constitutive promoter CaMV 35S SSU soybean promoter was strictly light dependent	Gitins <i>et al.</i> , 2000
Gene expressed in young stem tissue and load bearing regions	Greensleeves		<i>Brassica napus</i>	940 extA promoter	(-)940 extA promoter has an activity in apple stem comparable to that obtained with CaMV 35S. Its activity was lower in petioles (50%), roots (20%), and leaves compared to the activity of CaMV 35S	Gitins <i>et al.</i> , 2001
Gene expressed in vegetative tissues	Greensleeves		<i>A. rhizogenes</i> <i>Commelina</i> yellow mottle virus	RoIC promoter CoYMV promoter	The two promoters showed an activity lower than the CaMV 35S. RoIC promoter was less active than CoYMV promoter in apple These promoters are active in the vascular system, particularly the phloem	Gitins <i>et al.</i> , 2003
Gene expressed in response to pathogen attack	M.26 Royal Gala		<i>Potato</i>	GstI promoter	In the two apple genotypes, GstI exhibited a low level of expression after bacterial and fungal inoculation compared to CaMV 35S (15% and 8%, respectively). It is activated by salicylic acid but not by wounding	Malnoy <i>et al.</i> , 2007b
Chemical inducible and light-inducible promoter	M.26		Nd	XVE promoter	Promoter currently being evaluated	Norelli <i>et al.</i> , 2007

Selectable marker <i>Nonantibiotic- based selection</i>	M.26	Phosphomannose isomerase (<i>pmi</i>)	Nd	CaMV 35S	Mannose (2 g l ⁻¹) can be used as selection agent but the selection efficiency seems to be lower than that of kanamycin	Zhu <i>et al.</i> , 2004
	Pinova Pilot Elstar Regine	<i>pmi</i> <i>GFP</i>		CaMV 35S	Some putative transgenic lines were regenerated with the GFP gene as reporter gene Any transgenic lines were regenerated with the <i>pmi</i> gene as selectable marker	Flachowsky <i>et al.</i> , 2004
		<i>pmi UDP- glucose:galactose- 1-phosphate uridylyltrans- ferase (galT)</i> <i>Vt-ERE</i>	Nd		First regenerants were obtained, with the <i>pmi</i> gene as selectable marker, and tested gus positive No transgenic lines yet regenerated with the <i>galT</i> gene	Szankowski and Degenhardt, 2006; Degenhardt <i>et al.</i> , 2006
	Galaxy		<i>Vigna radiata</i>	CaMV 35S	Benzaldehyde (BA) is able to inhibit adventitious bud regeneration Ba can be used instead of kanamycin but the efficiency of the selection pressure is not yet proven	Chevreau <i>et al.</i> , 2007
Excision by recombination	Elstar	<i>Cre-lox</i> system			Antibiotic-resistance marker gene free transgenic Elstar apple lines have been produced	Schaart <i>et al.</i> , 2004
No selectable marker	M.26 Galaxy	None			Transgenic lines of M.26 and Galaxy were regenerated without any selectable marker with an efficiency of 22% and 12%, respectively	Malnoy <i>et al.</i> , 2007c

to drive expression of the *GUS* reporter gene was determined in two genotypes of apple: the fruit cultivar Royal Gala and the M.26 rootstock (Malnoy *et al.*, 2007d). In both apple genotypes, the *gst1* promoter exhibited a low level of expression after bacterial and fungal inoculation compared to the level obtained with the *CaMV* 35S promoter (15% and 8%, respectively). The *gst1* promoter was systematically activated in apple from the infection site with a fungal pathogen. It was also activated after treatment with salicylic acid but not after wounding. In apple, the *gst1* promoter is less active than the *CaMV* 35S promoter, but its pathogen responsiveness could be useful in driving the expression of transgenes to promote bacterial and fungal disease resistance.

Norelli *et al.* (2007) reported the use of a chemically induced promoter *XVE* in apple. The ability of this promoter to drive the *gus* gene in apple is under investigation.

Constitutive and nonspecific promoters such as *CaMV* 35S and *A. tumefaciens* nopaline synthase (*nos*) have been used as experimental tools to assess the effects of transgene expression. With such promoters, a gene is expressed in the majority of tissues throughout plant development. This lack of temporal and spatial regulation may be suitable for proof of concept experiments but has a number of potential drawbacks for use in genetically improved crops (Gittins *et al.*, 2000). Moreover there has been some discussion in the scientific press (Ho *et al.*, 1999) and the media as to the safety of using the *CaMV* 35S promoter in any transgenic plant strategy due to concerns regarding its unpredictable recombinogenic potential (Kohili *et al.*, 1999). To address the problems associated with constitutive promoters, Gittins *et al.* (2000, 2001, 2003) undertook a study on efficacy of various tissue-specific promoters in apple. They studied the level and location of expression in apple of the *GUS* reporter using promoters from *Rubisco* small subunit (*SSU*) genes of tomato and soybean (Gittins *et al.*, 2000), from a form of the *B. napus* extension A gene (*extA*) (Gittins *et al.*, 2001), and from *rolC* and *CoYMV* genes (Gittins *et al.*, 2003).

The *Rubisco* gene catalyzes the competing reactions of photosynthetic carbon fixation and photorespiration in higher plants and green algae. It is a multimeric enzyme composed of eight large and eight small subunits. The large subunit is

encoded by the chloroplast genome, whereas the *SSU* polypeptides are encoded by a nuclear gene family. Both of the *Rubisco* *SSU* promoters of tomato and soybean exhibited expression with half of the activity of the *CaMV* 35S promoter in apple tissues. This activity appeared to be localized in the leaf mesophyll and palisade cells of the photosynthetically active leaf (Gittins *et al.*, 2000). Both promoters would be appropriate for confining the expression of beneficial transgenes to green photosynthetic tissues. Effective leaf-specific promoters would also be useful in directing the expression of pest and disease resistance factors.

The *extA* gene of *B. napus* encodes one member of an extensin gene family. The *extA* transcript is highly expressed in roots, with lower levels in stems and petioles, and very little, if any, expression in leaves (Shirsat *et al.*, 1996). Extensin genes from a number of plant species are induced by wounding treatments (Elliott and Shirsat, 1998). Deletion analysis of the *extA* promoter localized the wound responsive elements to within the -940 to -3500 bp region (-940 *extA* promoter) (Elliott and Shirsat, 1998). The ability of the -940 *extA* promoter to drive expression of the *gus* reporter gene was determined in the apple genotype Greensleeves (Gittins *et al.*, 2001). In this genotype, the -940 *extA* promoter did not express very highly in roots compared to the *CaMV* 35S promoter. It is likely that those control elements responsible for root specificity are located outside the *extA* promoter fragment used in this study. However, the -940 *extA* promoter has strong activity in apple stems comparable to that obtained with *CaMV* 35S. This activity was lower in petioles (50%), and leaves compared to the activity of *CaMV* 35S. On the basis of the results of Gittins *et al.* (2001), there is the potential to use this promoter to drive transgenes whose gene products are active in stems to bring about dwarfing, or to alter lignin composition, both major goals of tree biotechnology.

The *rolC* gene and *Commelina* yellow mottle virus (CoYMV) are active in the phloem, and vascular parenchyma. The ability of the promoter to drive the expression of the reporter gene *gus* in the vascular system of apple was determined in the apple genotype Greensleeves (Gittins *et al.*, 2003). In Greensleeves both promoters showed activity in the vascular system, particularly in the phloem, but with lower activity than with *CaMV* 35S.

The entire group of heterologous promoters tested in apple showed similar patterns of expression as in their host plants.

2.2.2 Engineering disease resistance

The most important diseases of apple are fire blight, caused by the bacterium *E. amylovora* and scab, caused by the fungus *V. inaequalis*. Both diseases are favored by humid climates and cause significant losses in many apple-growing regions. Different strategies have been used to increase resistance to these two pathogens.

2.2.2.1 Fire blight

Fire blight is a disease of American origin and was first reported in the Hudson Valley of New York in 1784. It has been known as the major destructive bacterial disease of the *Maloideae* (pear, apple, and quince) and other members of the *Rosaceae* for over 200 years, and is in fact, the first plant disease proved to be of bacterial origin (Norelli *et al.*, 2003). This disease is caused by the necrogenic endobacterium *E. amylovora*, which is capable of infecting blossoms, fruits, vegetative shoots, woody tissues, and rootstock crowns. Upon entering plants through natural openings or wounds, the bacteria cause necrosis that develops quickly along the shoots to the main branches, producing the characteristic symptom of this disease: a necrotic shoot blight that can kill a tree in one season (Thomson, 2000). In nonhost plants, such as *Arabidopsis thaliana* or tobacco, *E. amylovora* elicits a hypersensitive response (HR) characterized by a rapid and localized collapse of tissues.

E. amylovora, *Enterobacteriaceae*, is a gram negative bacterium and its anatomy, physiology, and serology have been well described (Paulin, 2000). Twenty years ago, factors involved in its pathogenicity and virulence were identified. Transposon mutagenesis led to the identification of three key groups of genes responsible for pathogenicity: (1) The cluster of *dsp* genes (disease specific gene, Boucher *et al.*, 1987) is strictly required for pathogenicity (Gaudriault *et al.*, 1997; Bogdanove *et al.*, 1998b). Two *dsp* genes were isolated, *DspA* or *E*, which encodes a pathogenicity factor homologous to the *Avr E* gene

of *Pseudomonas syringae*. The *DspB* or *F* gene encodes a protein similar to a chaperone protein of pathogenic bacteria such as *Yersinia* and *Shigella* (Gaudriault *et al.*, 1997; Bogdanove *et al.*, 1998a, b). (2) The *ams* gene (amylovoran synthesis gene) is required for synthesis of extracellular polysaccharides (EPSs) (Belleman and Geider, 1992). (3) The *hrp* (hypersensitive reaction and pathogenicity gene) cluster is necessary for pathogenicity on host plants and HR elicitation on nonhost plants (Barny *et al.*, 1990; Kim and Beer, 2000). The *hrp* gene cluster has been characterized in several other pathogenic bacteria such as *Xanthomonas* and *Ralstonia* (Lindgren, 1997). This cluster encodes components of a type III secretion pathway (Hueck, 1998), and regulatory and secreted proteins. Today, at least seven proteins of *E. amylovora* are known to be secreted via the Hrp pathway: *DspA/E*, *OrfB*, *HrpW*, *HrpA*, *HrcQ*, *HrpJ*, and *HrpN_{Ea}* (Kim and Beer, 2000). *Harpin N_{Ea}* was the first secreted protein characterized by molecular analysis (Wei *et al.*, 1992). This protein is a 44 kDa glycine-rich protein, which lacks cysteine, is heat stable, and is able to induce an HR when purified and infiltrated into tobacco leaves. Besides three key pathogenicity factors, *E. amylovora* produces a siderophore belonging to the desferrioxamine family, which acts as virulence factor (Dellagi *et al.*, 1998).

The economic impact of fire blight is difficult to determine, as losses are rarely recorded when they are low (a few flower clusters on a few trees killed within a season) and a single outbreak can disrupt orchard production for several years. However, in recent years, fire blight has caused serious losses around the world (Norelli *et al.*, 2003). While outbreaks are sporadic in occurrence, they often result in significant losses when they do occur, in terms of trees damaged and killed, or loss of crops. In 2000, southwest Michigan experienced a severe fire blight epidemic and reported a \$42 million economic loss for the region that resulted in the removal of 300 000 apple trees covering approximately 2000 acres. Losses and costs in many other states and countries, such as New Zealand, Italy, and Washington State in 1998 were also very substantial.

The strategies of ribosomal DNA (rDNA) technology to improve the resistance to pathogens are aimed at producing incompatible interactions between the plant and the pathogen, by means

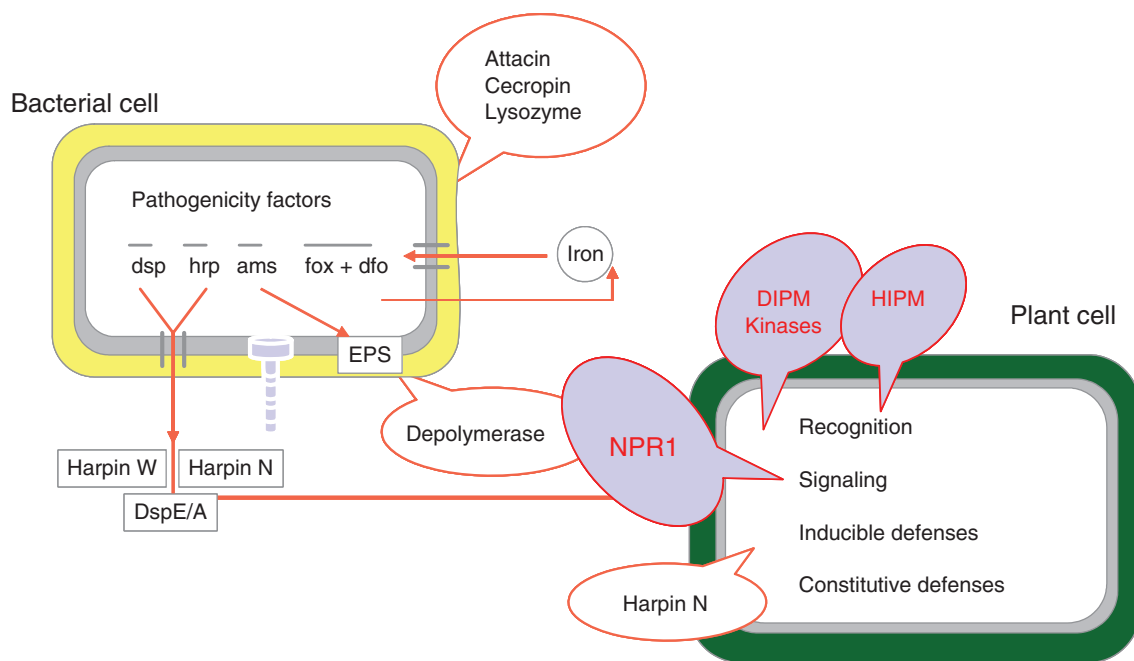

Figure 1 Drawing representing the different strategies used in apple for increased resistance to *Erwinia amylovora*

of restricting the multiplication of the pathogen in the plant after infection. These outcomes can be obtained in different ways: (1) production of antimicrobial proteins, (2) inhibition of bacterial pathogenicity factors, and (3) enhancement of natural plant defense. These three different ways have been used to increase resistance to fire blight (Figure 1; Table 2).

Production of antimicrobial proteins Antibacterial proteins are important components of the overall antimicrobial defense mechanisms of many groups of animals, including arthropods, amphibians, and mammals (Mourgues *et al.*, 1998). Probably acting in synergy, they have a bactericidal action on a large range of gram negative and gram positive bacteria. Genes encoding antimicrobial proteins that have been cloned and expressed in apple and pear in an attempt to confer resistance to fire blight disease include: attacin E, cecropins, and lysozymes (Table 2).

Attacins and cecropins are antimicrobial peptides found in the hemolymph of *Hyalophora cecropia* in response to bacterial infection (Hultmark *et al.*, 1980). These two peptides have no known enzymatic activity. They are active against the

membrane of gram negative bacteria. Attacin causes an increase in the permeability of the outer membrane (Carlsson *et al.*, 1991) and cecropin induced pore formation in the bacterial membrane (Flink *et al.*, 1989), which results in death of the bacterial cells. Attacin E and synthetic analogs of cecropin (SB-37, Shiva 1, and MB39) under the control of inducible (Pin2) and constitutive (CaMV 35S) promoters have been introduced into various apple genotypes to enhance resistance to *E. amylovora* (Table 2). These genes were reported to cause partial resistance to fire blight.

Attacin expression in apple trees in the greenhouse and in the field has significantly increased the level resistance to fire blight (Aldwinckle *et al.*, 1998, 2003a; Ko *et al.*, 2000). This increased fire blight resistance was reported to be correlated with the expression level of attacin (Ko *et al.*, 2000). The presence of a peptide signal, which allowed the secretion of attacin into the intracellular space, increased the resistance of the transgenic apple in spite of a lower attacin content (Ko *et al.*, 2000). Attacin E expression is increased when this gene is under the control of the alfalfa mosaic virus (AMV) translational enhancer (Ko *et al.*, 2000). Hanke *et al.* (2000), showed

similar increased resistance to fire blight when the attacin gene was expressed in different apple cultivars.

In 1997, approximately 120 field grown plants of 13 Royal Gala transgenic lines containing the cecropin SB-37 transgene were evaluated for their resistance following inoculation of vigorously growing shoot-tips with *E. amylovora*. In this test, several of the transgenic lines developed less disease than Royal Gala, but only transgenic line T245 (12% shoot length infected) was significantly more resistant than Royal Gala (67%). In addition, the cecropin B analog MB39 under the control of the wound-induced osmotin promoter from tobacco has been transferred to Royal Gala and few lines showed partial fire blight resistance (Liu *et al.*, 1998, 2001).

Lysozymes are bacteriolytic enzymes that have been characterized from phages, bacteria, fungi, plants, and animals (Jollès and Jollès, 1984). They are responsible for weakening the cell wall, leading to eventual lysis of bacteria cells (Düring, 1996). Some lysozymes also have chitinase activity (EC 3.2.1.14) resulting from random hydrolysis in the chitin. Their mode of action is such that they act only as bactericides to gram positive bacteria (Boman and Hultmark, 1987). However, they have displayed activity against gram negative bacteria when they act in synergy with other antimicrobial peptides (cecropin or attacin) (Boman and Hultmark, 1987).

Hanke *et al.* (2000) transferred the *T4 lysozyme* gene using pSR8-36 to Pinova apple. This gene was able to induce increased resistance in some transgenic lines in the greenhouse. Ko *et al.* (1998) cloned the pSR8-36 chimeric *T4 lysozyme* gene containing the α -amylase signal peptide into pBIN19 under the control of the enhanced 35S promoter with the AMV translational enhancer. Ko *et al.* (1998) also combined this chimeric *T4 lysozyme* gene with *attE* under control of the Pin promoter. These two constructs were introduced into the Galaxy apple (Aldwinckle *et al.*, 1998; Ko *et al.*, 1998). Some T4 lysozyme transgenics of Galaxy have shown increases in fire blight resistance in preliminary growth chamber tests (Ko *et al.*, 2002). However, transgenic lines containing both attacin and *T4 lysozyme* genes were not significantly more resistant than Galaxy transgenic for attacin or T4 lysozyme alone, indicating that there was no *in planta* synergy

between these two genes with respect to resistance to *E. amylovora* (Ko *et al.*, 2002).

Inhibition of bacterial pathogenicity factors Expression by the plant of any product inhibiting bacterial pathogenicity or virulence factors should lead to resistance or reduced susceptibility. In *E. amylovora* several of these factors are well known, and this knowledge had only started to be exploited to develop strategies for engineering resistance to fire blight. To date in apple, only one of these pathogenicity factors has been inhibited, the capsular EPS. The capsular EPS plays an essential role in pathogenicity. Indeed, the capsule functions not only to bind water, ions, and nutrients, but also as a protective layer to reduce possible recognition and response by the host (Romeiro *et al.*, 1981). This EPS can be naturally degraded by protein depolymerases of some bacteriophages. Hartung *et al.* (1988) have isolated an *EPS-depolymerase* gene from phage ϕ Ea1h. This gene has been integrated into the genome of two apple genotypes, Pinova (Hanke *et al.*, 2002, 2003) and M.26 (Borejsza-Wysocka *et al.*, 2007). In the work of Hanke *et al.* (2003), 61 out of 83 transgenic apple lines carrying the ϕ Ea1h depolymerase gene appeared significantly less susceptible than nontransgenic Pinova, after inoculation of detached leaves *in vitro*. Three lines appeared less susceptible than the control after inoculation of plants in the greenhouse. The partial fire blight resistance observed in these transgenic apple lines could be explained by the mode of action of depolymerase. Indeed, in capsule degradation assays using purified depolymerase, totally unencapsulated *E. amylovora* cells required high enzyme concentrations (Kim and Geider, 2000). Thus, they assumed that the amount of depolymerase produced in most of these transgenic clones is below the necessary threshold for sufficient destruction of EPS capsules at a high concentration of inoculum, but partly effective when the concentration of inoculum is lower. To achieve better control of fire blight in very susceptible apple cultivars, improvements in this strategy might be obtained by directing the depolymerase protein fused with a signal peptide to the apoplast and the intercellular space and by up-regulating this gene with a translational enhancer (e.g., AMV). Preliminary results have shown that in transgenic “M.26” apple, increased

resistance was observed when depolymerase gene is secreted into the intercellular space (Borejsza-Wysocka *et al.*, 2007).

Enhancement of natural plant defense Plant defense mechanisms are activated during incompatible and compatible reactions. However, in the case of a compatible interaction, the speed and level of expression of defense genes are insufficient to prevent disease development in the plant. Some strategies depend on blocking the progress of the pathogen in order to allow adequate activation of defense pathways of the plant (Figure 1).

During plant–pathogen interactions, pathogens secrete compounds called elicitors that induce plant defense mechanisms at variable speeds. These compounds when isolated from bacteria or fungi might be used to protect plants against their pathogens. These inducing substances can be classified into two groups: those interacting with the plant following the gene for gene model of Flor (1956) (*avr* genes) and those inducing the defense pathways of the plant. A bacterial *avr* gene conferred almost total resistance to plants expressing the corresponding resistance gene; in the case of *Arabidopsis* expressing the transgene *avrB* (Gopalan *et al.*, 1996) or *avrRpt2* (Mc Nellis *et al.*, 1998), resistance was expressed as an HR. But it is thought to be more likely that this type of resistance will be bypassed by pathogens compared with strategies using an elicitor with direct (PopA, Harpin N) or indirect (pectate lyase) action. Genetic engineering of induced defense mechanisms through the introduction of an elicitor gene into the plant genome has already been tested to generate resistance to pathogenic microorganisms. One approach is to place an elicitor gene under the control of a strictly pathogen-inducible promoter, in order to create local and limited cell death at the point of infection. This has been successfully achieved to protect tobacco from the oomycete *Phytophthora cryptogea*, by expression of either an oomycete elicitor (elicitin, Keller *et al.*, 1999) or a bacterial elicitor (PopA, Belbarhi *et al.*, 2001) under the control of the *hsr203J* promoter. A similar strategy, based on the expression of the Harpin N_{Ea} from *E. amylovora* under the pathogen-inducible promoter *gstI*, was tested on nonhost plants of fire blight, and decreased the infection of *A. thaliana* by the oomycete *Peronospora parasitica* (Bauer *et al.*,

1999) and potato by the oomycete *Phytophthora infestans* (Li and Fan, 1999). In order to create novel mechanisms for fire blight resistance in apple, some transgenic apple lines transformed with a construct containing the elicitor harpin N_{Ea} from *E. amylovora* with the inducible promoter *gstI* or the constitutive promoter CaMV 35S, respectively, were produced (Abdul-Kader *et al.*, 1999). Stable integration of Harpin N_{Ea} with the constitutive CaMV 35S promoter did not cause any detectable damage in the transgenic apple (Abdul-Kader *et al.*, 1999). Two years of field testing of own rooted plants of transgenic lines of M.26, containing the *harpin N_{Ea}* gene with the *gstI* promoter, showed a significant reduction in susceptibility to fire blight (Malnoy *et al.*, in preparation). Two of these lines showed a level of resistance equivalent to that of the apple rootstock M.7, which is partially resistant to fire blight. These transgenic lines can also help promote a better understanding of the role of harpin N_{Ea} in the induction of fire blight resistance in the transgenic clones. It will also be interesting to look at the behavior of these transgenic lines in response to other pathogens of apple.

Broad-spectrum resistance might also be achieved through manipulation of defense signaling molecules that act downstream of pathogen recognition. A plethora of defense signals have been identified using genetic, biochemical, and physiological approaches (Feys and Parker, 2000; McDowell and Dangel, 2000). Key players in the network include reactive oxygen intermediates (ROIs), nitric oxide (NO), salicylic acid (SA), the hormones ethylene, and jasmonic acid, and several proteins with presumed or demonstrated regulatory roles. In principle, each component of the signaling network represents a potential switch for activating the defense arsenal. This approach could provide broad-spectrum resistance if based on master regulators that activate the entire arsenal of defense responses. With these considerations in mind the *NPRI* gene (also known as *NIM1*) has emerged as a good candidate to provide broad-spectrum resistance. Some experiments have indicated that this gene is a key mediator of SAR. The *NPRI* gene encodes a protein that contains ankyrin repeats and displayed limited overall sequence similarity to the IKB human immune response regulator (Cao *et al.*, 1994, 1997; Ryals *et al.*, 1997). Sheng-Yang He and Qiao Lin

Jin (Michigan State University) cloned an *NPR1* ortholog, *MpNPR1*, from apple. This gene and the *Arabidopsis AtNPR1* gene were overexpressed under the control of pin2 or CaMV 35S promoters in two apple cultivars, Galaxy and M26, with the goal of increasing resistance to fire blight (Malnoy *et al.*, 2007b, c). The overexpression of *MpNPR1* activated the expression of some PR proteins (PR2, PR5 PR8) and increased resistance to fire blight in growth chamber tests. Preliminary results demonstrated that the cv. Galaxy clones with an additional copy of *MpNPR1*, under the control of the inducible promoter pin2, had a ca. 40% reduction in symptoms compared to the control (Malnoy *et al.*, 2007b, c).

In the past decade, the molecular bases of the interactions that determine pathogen recognition by the host plant cell have been clearly demonstrated, resulting in the cloning of both the avirulence (*avr*) and the corresponding resistance (*R*) genes. *E. amylovora* secretes the DspE pathogenesis factor that has some similarities to an Avr protein. Its apparent function as an Avr protein in the plant pathogen interaction seems to indicate a key role for it in disease development. Using a yeast two hybrid screen, Meng *et al.* (2006) identified four similar, leucine-rich-repeat (LRR), receptorlike serine/threonine kinases, from apple. The genes encoding the four DspE-Interacting Proteins of *Malus* (*DIPM* genes) are conserved in all hosts of *E. amylovora* tested, but not in tested nonhost plants. Interaction between the *DIPMs* and DspE is thought to be involved in disease development. With the aim of silencing the *DIPM* genes and preventing disease-causing interaction with DspE, 400 bp sense sequences from nonconserved regions of each gene, with homology among each other of <50% were introduced into the genome of the apple cv. Galaxy (Borejsza-Wysocka *et al.*, 2006). In addition, three constructs containing the four 400 bp sequences in tandem, a full length sense sequence of one gene and a hairpin sequence of that gene were also introduced into Galaxy apple. Reverse transcriptase PCR (RT-PCR) assays of the transgenic plants for transcript expression of the target *DIPMs* have shown evidence of silencing at the mRNA level in some lines. Some of the transgenic lines have also been evaluated for resistance to fire blight by inoculation of shoots of own-rooted potted plants with the virulent strain Ea273 of

E. amylovora. Preliminary results indicate that some lines have increased resistance (Borejsza-Wysocka *et al.*, 2004, 2006).

Using the same yeast two hybrid screen, Beer *et al.* (2006) were able to identify one protein that interacts with the Hrp N elicitor factor of *E. amylovora*. This small protein (60 aa) has a functional signal peptide and is associated with plant plasma membranes. With the aim of silencing the gene encoding for the HrpN-Interacting Protein of *Malus* (*HIPM*), an RNai construct containing the full length of this gene was introduced into the apple cv. Galaxy. Preliminary results showed partial resistance to fire blight (M. Malnoy, personal communication).

2.2.2.2 Apple scab

Apple scab, which is caused by the ascomycete *V. inaequalis* (Cke.), is the most important fungal disease of apple in most apple-growing regions with high spring and summer rainfall. This fungus attacks the foliage and the fruit of the apple tree. The infection of immature apples causes severe fruit drop, resulting in reduced yield, and later infections result in unmarketable fruits. The control of this disease in commercial orchards can require up to 15 fungicide treatments per year. However, because of increasing fungicide resistance within the pathogen, use of modern specific fungicides must be strictly limited and/or alternated. An alternative approach is growing resistant cultivars that use scab-resistance genes from small-fruited wild species. However, the production of high quality resistant cultivars by classical breeding is difficult because of the long juvenile phase and self-incompatibility of apple. Starting with the wild species *Malus floribunda* 821 carrying the *Vf* gene for resistance to apple scab, breeders have developed many scab-resistant cultivars, but few have met with any measure of commercial success mainly because of lack of high quality and/or storage ability. The direct transfer of a scab-resistance gene offers a new alternative for cultivar improvement.

Several groups have attempted to improve the scab resistance of highly susceptible apple cultivars such as Gala (Jensen *et al.*, 2002; Belfanti *et al.*, 2004), Galaxy (Faize *et al.*, 2003, 2004; Malnoy *et al.*, 2007e), Jonagold (De Bondt *et al.*, 1999), and McIntosh (Bolar *et al.*, 2000;

Malnoy *et al.*, 2007e) or partially resistant cultivars such as Ariane (Faize *et al.*, 2003, 2004), by the integration of heterologous antifungal genes (*chitinases*, *Amp1*, *AFP2*, *puroindoline*, or *hordothionine*) or *Vf* gene orthologs.

The biocontrol fungus *Trichoderma atroviride* (previously *Trichoderma harzianum*) produces many chitinolytic enzymes, including endochitinase, which randomly cleaves chitin, a major component of the fungus cell wall. *Trichoderma* endochitinase encoded by the gene *ech42* inhibits spore germination and hyphal elongation. Bolar *et al.* (2000) obtained several lines of the susceptible McIntosh apple with varying levels of *ech42* expression. Some of the transgenic lines exhibited increased resistance to *V. inaequalis*. However, transgenic lines with high endochitinase activity had reduced vigor. Similar results were also observed by Faize *et al.* (2003) when the *ech42* gene was introduced into the apple cultivars Galaxy and Ariane. This reduction of growth appeared to be associated with lignin content, peroxidase, and glucanase activity in the transgenic lines (Faize *et al.*, 2003). Endochitinase from the *ech42* gene interacts synergistically with other chitinolytic enzymes of *T. atroviride* such as N-acetyl- β -glucosaminidase (exochitinase *nag70*). Bolar *et al.* (2001) and Faize *et al.* (2003) studied transgenic lines of three different apple cultivars expressing *ech42* and *nag 70* alone or in tandem and demonstrated *in planta* synergy between these enzymes. Indeed, the transgenic lines expressing these two genes were more resistant than plants expressing either single enzyme at the same level.

Significant increase of resistance to *V. inaequalis* was also observed with the expression of other antifungal genes. Expression of the puroindoline B gene, a member of the plant lipid transfer proteins (LTPs), in two apple cultivars (Ariane, which is resistant to races 1–5 and susceptible to races 6 and 7, and Galaxy, which is susceptible to all races of scab) induced reduction of symptoms after inoculation with *V. inaequalis* race 6 of 55% and 64% in the most resistant transgenic lines of Galaxy and Ariane, respectively (Faize *et al.*, 2004). Preliminary results showed that the *hordothionin* (Jensen *et al.*, 2002), *Ace-AMP1*, and *Rs-AFP2* (De Bondt *et al.*, 1999) genes have potential for increasing resistance of apple to *V. inaequalis*.

A scab-resistance locus *Vf* was identified in the wild apple species, *M. floribunda* 821, and has been

widely introgressed into susceptible apple cultivars (Korban, 1998). The *Vf* locus confers resistance to five races of *V. inaequalis*, but not to races 6 and 7, recently identified in Europe. A cluster of four receptorlike sequences has been identified at the *Vf* locus, which resembles the *Cf* resistance genes in tomato (Vinatzer *et al.*, 2001; Xu and Korban, 2002). Three of them, designated *Vfa1*, *Vfa2*, and *Vfa4*, have intact ORFs, whereas, the fourth one, *Vfa3*, is an obvious pseudogene. Differential expression has been observed among the four *Vf* orthologs during leaf development, whereby *Vfa1*, *Vfa2*, and *Vfa3* are highly expressed in immature leaves, but only slightly detectable in mature leaves; whereas, *Vfa4* is expressed in immature leaves, and highly expressed in mature leaves (Xu and Korban, 2002). Barbieri *et al.* (2003) and Belfanti *et al.* (2004) have proved that overexpression of the *Hcrvf2* (= *Vfa2*) gene, under the control of the constitutive promoter CaMV 35S, was sufficient to confer scab resistance to a susceptible apple cultivar. However, this resistance is specific to *V. inaequalis* races, effective toward races 1–5, but not toward race 6 (Silfverberg-Dilworth *et al.*, 2005b). Malnoy *et al.* (2007e) showed also that the gene *Vfa2* is sufficient to confer partial resistance to *V. inaequalis* in Galaxy and McIntosh when it is expressed under the control of its own promoter. They also showed that the *Vfa1* gene is able to confer partial resistance to a mixture of apple scab races (race 1–5). These two studies showed that the *Vfa1* and *Vfa2* genes are involved in the resistance of apple scab in apple. In contrast, the *Vfa4* gene is not involved in resistance to apple scab. Indeed, the Galaxy and McIntosh transgenic lines expressing the *Vfa4* gene were as, or more susceptible to or than the control (Malnoy *et al.*, 2007e). It will be interesting to transform some scab susceptible apple cultivars with the *Vfa1* and *Vfa2* genes in tandem, to determine their synergetic effect. It will also be informative to study the specificity to the different *V. inaequalis* races of Galaxy and McIntosh transgenic lines expressing *Vfa1* or *Vfa2*.

2.2.2.3 Other apple pathogens

Resistance in apple to two other diseases (crown gall and *Alternaria* blotch) and to an insect (lightbrown apple moth) has been reported to be increased by genetic engineering.

Lightbrown apple moth (LBAM), *Epiphyas postvittana*, is a serious pest of pome and stone fruits and of many other horticultural crops, including grape vine, citrus, kiwifruit, berry fruits, avocados, and some vegetable and flower crops in New Zealand (Wearing *et al.*, 1991). It commonly causes superficial fruit damage, and this, together with the presence of larvae, forms the basis of a quarantine problem in exported fruit. LBAM also occurs in Australia, New Caledonia, Hawaii, England, and other parts of Europe, where it is found on apples, pears, and oranges (Dickler, 1991). Markwick *et al.* (2003) produced some Royal Gala transgenic lines expressing the *avidin* or *streptavidin* gene. Enzyme-linked immunosorbent assay (ELISA) assays showed that *avidin* expression ranged from 1.9 to 11.2 μM and *streptavidin* expression ranged from 0.4 to 14.6 μM . Expressed at these levels, both biotin-binding proteins conferred a high level of insect resistance on transformed apple plants to larvae of the LBAM (Markwick *et al.*, 2003). Mortality of LBAM larvae was significantly higher ($P < 0.05$) on three *avidin*-expressing (89.6%, 84.9%, and 80.1%) and two *streptavidin*-expressing (90% and 82.5%) apple lines than on nontransformed control plants (14.1%) after 21 days. Weight of LBAM larvae was also significantly reduced by feeding on all apple shoots expressing *avidin* and on apple shoots expressing *streptavidin* at levels of 3.8 μM and above (Markwick *et al.*, 2003).

Crown gall is a significant agricultural problem worldwide. *A. tumefaciens*, a ubiquitous soil bacterium (Bouzar and Moore, 1987), causes this disease in a wide variety of plants including fruit and nut trees, grapevines, cane berries, chrysanthemum, rose, and other nursery crops (Pinkerton *et al.*, 1996). *A. tumefaciens* genetically transforms plant cells to grow as tumors; therefore, after a few hours of infection the disease will progress even if the tumor-inducing bacteria are killed with antibiotics. Thus, prevention is the only effective way to control crown gall. Tumors on stems and leaves result from excessive production of the phytohormones auxin and cytokinin in plant cells genetically transformed by *A. tumefaciens*. High phytohormone levels result from expression of three oncogenes transferred stably into the plant genome from *A. tumefaciens*: *iaaM*, *iaaH*, and *ipt*. The *iaaM* and *iaaH* oncogenes direct auxin biosynthesis, and the *ipt* oncogene causes

cytokinin production. In contrast to other tissues, roots do not respond to high cytokinin levels, and auxin overproduction is sufficient to cause tumor growth on roots. Inactivation of *iaaM* abolished gall formation on apple tree roots. Transgenes designed to express double-stranded RNA from *iaaM* and *ipt* sequences in Jonagold prevented crown gall disease on roots of transgenic apple trees (Viss *et al.*, 2003). Thus, silencing the *A. tumefaciens iaaM* oncogene provides a simple and effective means to prevent crown gall disease in crop plants such as apple trees.

Alternaria blotch, caused by *Alternaria mali*, is a serious disease of apple in Japan, Korea, and China. It also occurs in Zimbabwe and has been found in the United States. *A. mali* is responsible for the formation of lesions on leaves in late spring and summer. These lesions are small, round, blackish spots, gradually enlarging to 2–5 mm in diameter, with a brownish purple border. Fruit infections are uncommon, except in very susceptible cultivars. In order to increase the resistance to this disease, Kim *et al.* (2007) introduced the gene *Rab*, known to participate in general defense signaling pathways in plant cells, into the McIntosh apple genome. Preliminary data show that all the transformants have smaller disease lesions and spot size than the control (Kim *et al.*, 2007).

In conclusion, increased resistance to pathogens is possible via genetic engineering. The concept was proven first by using genes from different organisms such as insects, animals, and bacteria. Due to the concern of the public, the use of genes from *Malus* will be more appropriate. One strategy that can be used effectively for increased pathogen resistance is the use of specific apple genes, which confer resistance to several pathogens, such as the *NPR1* gene, which increased resistance of apple to fire blight, apple scab, and cedar apple rust (Malnoy *et al.*, 2007b, c).

2.2.3 Environmental stress resistance

Iron is an essential element for all living organisms. Although abundant in soils, iron often forms highly insoluble ferric-hydroxide precipitates with limited availability for plants, especially crops grown on calcareous soils (Guerinot and Yi, 1994). Apple trees grown on calcareous soils often

show chlorosis due to iron deficiency; this is the case with most apple trees grown in China. The chlorosis of apple trees grown under iron deficiency conditions can be easily avoided by grafting the scion on apple rootstocks with iron-deficiency tolerance. In higher plants iron is acquired from the soil through the coordinated action of H^+ -ATPases, membrane-bound Fe^{3+} -chelate reductase and Fe^{2+} specific cation transporters (Qu *et al.*, 2005). Several of these genes involved in iron assimilation have been cloned (Eckhardt *et al.*, 2001; Li *et al.*, 2006) and some have been used to improve iron deficiency tolerance (Goto *et al.*, 1998, 1999, 2000). Qu *et al.* (2005) reported that by introducing the iron transporter *LeIRT2* into the Balenghaitang rootstock they increased the tolerance of transgenic lines to iron deficiency. Plants in hydroponically cultivated transgenic lines weighted 21–34% greater than control plants.

During exposure to biotic and abiotic stresses, molecular oxygen can undergo reactions that result in the formation of ROIs. ROIs are highly destructive to lipids, nucleic acids, and proteins and the resulting injury is referred to as oxidative stress. In fruit crops, oxidative stress plays a role in freezing injury, sunburn, and physiological scald. Artlip *et al.* (2006) were able to increase the resistance of apple to heat and low temperature by overexpressing the cytosolic ascorbate peroxidase (*APX*) gene. Transgenic lines exhibited variability in their levels of *APX* enzyme activity compared to the control, and also displayed varying degrees of increased resistance to high and low temperature stress. Resistance to freezing injury was 1–3° greater, and resistance to acute heat stress up to 7° greater in transgenic lines (Artlip *et al.*, 2006).

2.2.4 Carbohydrate metabolism in apple (Table 2)

In addition to sucrose and starch, Sorbitol is accumulated by apple plants. Sorbitol, the sugar alcohol of glucose, is the predominant sugar found in apple. It is synthesized in mature leaves and translocated to fruit, where it is converted to fructose. The sugar alcohol sorbitol appears to be widely distributed in nature. It can be found in species of bacteria, insects, animals, yeasts, algae, fungi, and higher plants. However, certain woody members of the Rosaceae family, including

Malus, *Pyrus*, *Prunus*, and *Sorbus* spp. appear to be unique in the entire plant kingdom with respect to their ability to synthesize, accumulate, and degrade sorbitol. In apple trees, sorbitol is believed to be the major photosynthetic product, translocated from mature leaves to growing tissues, such as fruits and young leaves. At the biochemical level, sorbitol metabolism occurs as a result of two significant reactions: one results in the formation of sorbitol 6-phosphate from glucose 6-phosphate by aldose 6-phosphate reductase in photosynthetic tissues, referred to here as sorbitol 6-phosphate dehydrogenase (*S6PDH*); the second results in the conversion of sorbitol to fructose by sorbitol hydrogenase (*SDH*) in skin tissues. The *S6PDH* gene from apple was cloned by Kanayama *et al.* (1992) and its expression in transgenic tobacco was correlated with sorbitol synthesis and concentration (Tao *et al.*, 1995). When the *S6PDH* apple gene was overexpressed in the apple genotype Orin, transgenic lines with integration of several copies of the *S6PDH* showed a reduction in activity of this gene caused by cosuppression (Kanamaru *et al.*, 2004). This reduction of activity was accompanied with a reduction in sorbitol level in the transgenic lines but showed a sixfold to sevenfold increase in sucrose compared with the nontransgenic plants. However, these transgenic lines ceased growth in early summer compared to the control. This suggests that growth of the shoot apex may be stopped by a deficiency of sugar supply to the sink organ, because apple uses sorbitol rather than sucrose as the main translocated sugar (Kanamaru *et al.*, 2004). Conversely, transgenic Orin apple lines, which had integrated few copies of the *S6DPH* genes, showed increased *S6PDH* activity and had increased levels of sorbitol and sucrose content (Kanamaru *et al.*, 2004).

When the *S6PDH* apple gene was expressed in antisense in the apple Greensleeves, its activity was decreased as was the accumulation of sorbitol. However, such transgenic lines had an increased content of sucrose and starch at both dusk and predawn (Cheng *et al.*, 2005). The sorbitol to sucrose ratio in leaves is reduced by 90% and in phloem exudates by 75%. The fruit accumulated more glucose and less fructose, starch and maleic acid, with no overall difference in weight and firmness (Teo *et al.*, 2006). Silencing leaf sorbitol synthesis affects the fruit quality such as glucose,

fructose, starch, and malic acid accumulation (Teo *et al.*, 2006). In these transgenic lines the sorbitol dehydrogenase gene is down-regulated whereas the sucrose synthase activity is up-regulated in the shoot tips with decreased sorbitol synthesis, leading to homeostasis of vegetative growth (Zhou *et al.*, 2006).

Modification of the sorbitol pathway in apple may clarify understanding of the regulation of photosynthesis and carbon partitioning by sorbitol synthesis. In conclusion, these two studies show that the photosynthetic process in sorbitol synthesizing species has considerable plasticity. When sorbitol synthesis is decreased by antisense or sense inhibition of *S6PDH*, cytosolic fructose-1,6-biphosphatase activity is down-regulated to reduce the carbon flux to the cytosol, and starch synthesis in the chloroplast is consequently up-regulated.

Suleman and Steiner (1994) have proposed a model to explain the fire blight susceptibility of tissue based upon sorbitol concentration. According to the model, increases in sorbitol concentration result in increasingly negative solute potentials, which have negative effects on the growth of *E. amylovora*, thus rendering these tissues more resistant. However, this hypothesis has not been proved, and evidence indicates it may not be correct (J.L. Norelli, personal communication).

2.2.5 Ethylene biosynthesis in apple

Ethylene is an important plant growth regulator that affects diverse plant processes including fruit ripening, fruit flavor composition, senescence, and response to biotic and abiotic stress. The biosynthesis of ethylene occurs in two enzymatic steps; in the first reaction, S-adenosyl methionine is converted to ACC (1-aminocyclopropane-1-carboxyl acid) by ACC synthase (ACS), and then in a second reaction, ACC is catalyzed by ACC oxydase (ACO) to produce ethylene. During ripening, the expression of *ACS* and *ACO* genes and the activity of their encoded enzymes govern the rate of ethylene production (Dandekar *et al.*, 2004). ACS regulates the rate limiting step in ethylene production (Yang and Hoffman, 1984) but ACO can also play a regulatory role (Gray *et al.*, 1992). Both enzymes have been well characterized and have

been cloned from apple (Dong *et al.*, 1991, 1992). These two genes have been expressed in antisense configuration in the apple Greensleeves (Dandekar *et al.*, 2004; Defilippi *et al.*, 2004, 2005a, b) and the cv. Royal Gala (Hrazdina *et al.*, 2003) (Table 2). From these two studies apple trees with down-regulation of ethylene have been produced. Hrazdina *et al.* (2003) reported a reduction in softening in some Royal Gala transgenic apple trees in which ACS had reduced activity. Dandekar *et al.* (2004) confirmed that transgenic lines that had a higher or lower ethylene production rate than the control have a correspondingly altered storage potential for their fruit. The availability of these lines suppressed in ethylene biosynthesis allowed the identification of events under ethylene control, such as fruit softening, external color development, and ester accumulation. The Greensleeves transgenic apple with suppressed ethylene biosynthesis permitted Defilippi *et al.* (2004) to analyze the role of ethylene in regulating overall flavor of apple fruits. Flavor components were differentially regulated in response to the suppression of both ethylene biosynthesis. Headspace analysis of aroma production showed a reduction in ester and alcohol production in the ethylene suppressed lines (Defilippi *et al.*, 2004). However, no major differences were observed in the concentrations of aldehyde volatiles. Other flavor metabolites that showed an ethylene-dependent pattern were organic acids and sugar (glucose and fructose) (Defilippi *et al.*, 2004). As for aroma volatile-related enzymes, Defilippi *et al.* (2005a, b) found that the acyltransferase (ATT) enzyme is under ethylene regulation and seems to play a role in determining ester formation.

These transgenic apple trees suppressed in ethylene biosynthesis were helpful in understanding the role of ethylene biosynthesis in fruit ripening and aroma formation, and will provide further understanding about the role of ethylene.

2.2.6 Dwarfism and rooting ability in apple rootstocks

Dwarfing characteristics of fruit tree rootstocks are of great importance for commercial production. Production per area of high quality fruits is greatly increased by the best dwarfing rootstocks.

Dwarfing rootstocks are useful for high-yield fruit production because trees can be planted closely together and labor is reduced because the apples can be harvested without using a ladder. Rootstocks like M.9 (dwarf) have been developed for this purpose. Some rootstocks are too vigorous to be used for commercial purposes and several dwarf rootstocks have problems with adaptability (Zhu *et al.*, 2001a). Some current projects are being conducted to improve apple rootstocks by introducing genes able to increase the dwarfing effect without affecting their rooting ability (Zhu *et al.*, 2001a, b). Several genes that cause reduced growth have been identified (Jasik *et al.*, 1997). The *rol* rootling (*A*, *B*, *C*, and *D*) genes from *A. rhizogenes* and the plant phytohormones genes have been shown to exert dwarfing properties (Jasik *et al.*, 1997).

The *rolB* gene has been found to be the most effective of the *rol* genes in promoting improved root formation; this gene has been applied in genetic transformation to improve adventitious rooting of some recalcitrant plants (Rugini *et al.*, 1991; Nilsson *et al.*, 1997). It has been successfully expressed in several apple rootstocks: M.26 (Welander *et al.*, 1998), M.9 (Zhu *et al.*, 2001b), and Jork9 (Sedira *et al.*, 2001, 2005; Pawlicki-Jullian *et al.*, 2002) and in the apple cultivar Florina (Radchuck and Korkhovoy, 2005). Resulting transgenic apple rootstocks and cultivar showed enhanced rooting in general, and an increased number of roots per explant (Welander *et al.*, 1998; Sedira *et al.*, 2001; Zhu *et al.*, 2001b; Pawlicki-Jullian *et al.*, 2002; Radchuck and Korkhovoy, 2005). However, growth was reduced in some rootstocks compared to the controls (Zhu *et al.*, 2001b; Pawlicki-Jullian *et al.*, 2002). In contrast, the transgenic apple Florina does not show any phenotypical difference after several months of growth *in vitro* or in the greenhouse compared to the control (Radchuck and Korkhovoy, 2005). The possible explanation of the differential effect of *rolB* on growth may be that Radchuck and Korkhovoy (2005) grew plants for 2 years, whereas Zhu *et al.* (2001b) grew them for 4 months and under a limiting supply of nutrients compared with steady-state nutrient supply conditions (Zhu and Welander, 2000). The apple rootstocks expressing the *rolB* gene are more sensitive to auxin (IBA) compared to the controls (Zhu *et al.*, 2001b; Sedira *et al.*, 2005). Zhu *et al.*

(2001a) also reported that the expression of the *rolA* gene increased sensitivity to auxin of the transgenic M.26 lines compared to the controls. Expression of *rolA* altered the growth capacity of transgenic M.26 (Holefors *et al.*, 1998) and A2 (Zhu *et al.*, 2001a). Some of these transgenic rootstocks showed a reduction in length, leaf area, and dry weight. Similar results were observed with the expression of either the *rolC* or *phytochrome B* gene in the apple rootstocks Marubakaidou (Igarashi *et al.*, 2002) and M.26 (Holefors *et al.*, 2000), respectively.

A delay in flowering and strongly reduced fertility had been previously described for some *rolA* transgenic plants (Tepfer, 1984; Sun *et al.*, 1991). However, this was not observed in the apple cv. Gravenstein grafted on the *rolA*-transformed M.26 rootstock (Zhu *et al.*, 2001a). Gravenstein flowered on both the *rolA*-transformed rootstock and on the nontransformed rootstock in the second year after grafting, and flowers were normal in greenhouse (Zhu *et al.*, 2001a). In apple, the side effects of the *rolA* gene might not be transmissible to a scion cultivar, as shown by the preliminary results of Zhu *et al.* (2001a). Currently, Zhu *et al.* (2007) have reported that the transgenic rootstocks A2-*rolA*, M.26-*rolB*, and M9/29-*rolB*, grafted with different apple cultivars are already in field trials to evaluate effects of rootstocks on growth and development of scion cultivars, and the possible transport of the *rolB* protein from rootstock to scion cultivars. Their preliminary results showed that, for the same cultivar, no differences in bud break, flowering, and flower numbers were found between the transgenic and nontransgenic rootstocks. The plant height and stem diameter were reduced for the vigorous cultivars grafted on the *rolB* rootstocks compared to the nontransformed rootstocks (Zhu *et al.*, 2007). In addition, no transgene was found in the nontransformed scion cultivars (Zhu *et al.*, 2007).

2.2.7 Other fruit traits

A significant problem with fresh-cut or juice-processed apples is enzymatic browning, a widespread problem in the food industry. The browning reaction is due to enzymatic action, caused by the polyphenoloxidase (PPO). PPO is considered to be located in plastids and physically

separated from its phenolic substrates that are mainly located in vacuoles. When plant tissues are damaged by cutting, bruising, or invasion by parasites, this compartmentalization is lost and PPO comes into contact with phenolic substrates (Waughn and Duke, 1984). In apple, PPO is mainly located around the core of the fruit, the location corresponding to the most intense browning (Murata *et al.*, 1993). A PPO cDNA (complementary DNA) was isolated from apple peel by Boss *et al.* (1995), showing that the PPO mRNA accumulated in immature fruits and wounded tissues. Haruta *et al.* (1998) isolated two genomic DNAs encoding apple PPOs, and showed that PPOs in the Rosaceae family were very similar by both molecular and immunological criteria (Haruta *et al.*, 1999). By using antisense methods, Murata *et al.* (2000, 2001) were able to repress the expression of the apple PPO gene. The silencing of this gene induced in the transgenic apple has lower browning potential (Murata *et al.*, 2000, 2001). Antisense expression of the PPO will need to be targeted to fruit tissue to prevent interference with PPO expression elsewhere in the plant that may be important for disease/pest resistance.

Polyphenol constituents derived from fruits like apple are more effective antioxidants *in vitro* than vitamins C and E, and thus may be more valuable for protection *in vivo*. Therefore, the active ingredient in “an apple a day keeps the doctor away” may well be the phytochemical component of the apple fruit. The phytochemical components include flavonoids, phenylpropanoids, and phenolic acids and have been highlighted as important contributing factors in the antioxidant activity in our diet (Rice-Evans *et al.*, 1997; Lee and Lee, 2003; Heo *et al.*, 2004). In apple, flavonols like quercetin and flavones like rutin may be important (Rice-Evans *et al.*, 1997). Indeed, quercetin derived from apple has a potential anticarcinogenic and antineuroprotective effects (Lee *et al.*, 2005). Stilbene synthase is an enzyme responsible for the synthesis of phytoalexin resveratrol. The production of resveratrol is related to fungal infection (Liswidowati *et al.*, 1991) and abiotic stress (Chung *et al.*, 2003; Rudolf and Resurreccion 2005) such as UV light and ozone. Stilbenes, in general, and resveratrol, in particular, are biologically active compounds, which have antifungal activities against various pathogens (Adrian *et al.*, 1997), among them

V. inaequalis (Schulze *et al.*, 2005). In addition to these implications for disease resistance, resveratrol and its glycosides have attracted interest as health promoting agents because of their antiinflammatory, estrogenic antiplatelet, and anticarcinogenic activities (Bertelli *et al.*, 1995; Jang *et al.*, 1997; Manna *et al.*, 2000). The biological and pharmacological activities of resveratrol are thought to be due to strong antioxidant properties. Due to the fact that apple has long been recognized as a great source of antioxidants, the synthesis of resveratrol in transgenic apple would expand the antioxidant capacity and could therefore be regarded as an additional factor for improving the intrinsic quality of the fruit. Szankowski *et al.* (2003) have produced transgenic apple plants expressing the *Stilbene synthase* gene from grapevine under the control of its own wound-, pathogen-, and UV-inducible promoter. Under greenhouse conditions, these transgenic apple lines are phenotypically normal, and flowered within the first and second years after grafting (Ruhmann *et al.*, 2006). Transgenic apple fruit was phenotypically indistinguishable from nontransgenic fruit of the same cultivars (Ruhmann *et al.*, 2006). The *S. synthase* gene is expressed in the fruit skin and in the flesh after promoter induction. The introduction of this novel pathway did not dramatically influence the accumulation of other phenolic compounds naturally present in apple fruits (Ruhmann *et al.*, 2006). Resveratrol was modified by the addition of a sugar in both vegetative and fruit tissues. Because of the high antioxidant activity of resveratrol, its synthesis in apple will contribute to fruit quality and might also have positive effects on fruit stability during storage (Ruhmann *et al.*, 2006).

Polygalacturonases (PGs) are expressed in a wide range of tissues and developmental stages in plants and are encoded by relatively large gene families. PGs are associated with fruit ripening, cell separation processes such as leaf and flower abscission, pod and anther dehiscence, pollen grain maturation, pathogen defense, plant host interactions, and processes of cell expansion, growth, and xylogenesis (Hadfield and Bennett, 1998; Torki *et al.*, 1999). A PG enzyme in ripe apple fruit has been isolated and biochemically characterized as an endo-PG (Wu *et al.*, 1993). The corresponding cDNA (*MdPG1*) was isolated

from Golden Delicious (Atkinson, 1994) and was shown to hybridize to an mRNA present in ripe fruit but not in developing fruit or flowers (Atkinson *et al.*, 1998). This gene, *MdPG1*, was overexpressed in apple with the expectation that disruption of cell wall metabolism would occur in the ripening fruit (Atkinson *et al.*, 2002). However, Atkinson *et al.* (2002) observed that *MdPG1* overexpression in transgenic apple led to a range of novel phenotypes. These phenotypes included silvery leaves and premature leaf shedding due to reduced cell adhesion in leaf abscission zones. Mature leaves had malformed and malfunctioning stomata, disturbed water relations, and a brittle leaf phenotype (Atkinson *et al.*, 2002). The modification of apple trees by a single *PG* gene offered Atkinson *et al.* (2002) a new and unexpected perspective on the role of pectin and cell wall adhesion in leaf morphology and stomatal development.

Allergy to apple fruits is a common phenomenon in patients with birch pollen allergy. Approximately 90% of patients allergic to birch pollen have IgE antibodies against the birch pollen allergen Bet v 1 (Mari *et al.*, 2003). This allergen belongs to a group of pathogenesis-related proteins, more specifically the PR10 proteins (Pühringer *et al.*, 2000). Many plant foods, in particular fruits and tree nuts, contain homologous proteins that are recognized by the same Bet V 1-specific IgE antibodies. In apple, this allergen was designated Mal d 1 (Vanek-Krebitz *et al.*, 1995). Approximately 70% of patients allergic to birch pollen have been reported to have adverse reactions to apple as a consequence of the cross-reactive IgE antibodies (Ebner *et al.*, 1991). Although birch pollen-related apple allergy is almost exclusively mild and restricted to the oral cavity, most patients allergic to apples avoid the fruit in their diet (Gilissen *et al.*, 2005). Related fruits of the Rosaceae family, such as pear, cherry, and peach can also induce adverse reactions on the basis of the same cross-reactive IgE antibodies (Ortolani *et al.*, 1988). Therefore, avoidance often results in deprivation in the diet of a wide range of common plant foods that have important nutritional value. Production of an apple with a significant reduction of the overall expression of *Mal d 1* from existing economically successful cultivars seems to be an attractive approach.

Gilissen *et al.* (2005) chose the approach of RNA interference (RNAi) for post-transcriptional silencing of the gene *Mal d1*. They have isolated one *Mal d 1* gene from Gala and transformed the Elstar apple cultivar with an *Mal d 1* RNAi vector. Normally it takes 3–5 years to grow an apple fruit-producing tree from seed or *in vitro* culture. Because *Mal d 1* genes are expressed in leaves as well as in the apple fruit, Gilissen *et al.* (2005) were able to evaluate *Mal d 1* gene silencing in the leaves of young apple shoots growing *in vitro*. Their results showed a reduction of expression of the *Mal d 1* by immunoblotting. This translated into significantly reduced *in vivo* allergenicity (Gilissen *et al.*, 2005). These observations support the feasibility of production, by gene silencing, of apple cultivars hypoallergenic for *Mal d 1* (Gilissen *et al.*, 2005). These data will need to be confirmed further by analyzing the expression of *Mal d 1* in transgenic fruit and by testing their allergenicity. *Mal d 1* silenced plants must also be evaluated for undesirable reduction in disease resistance.

2.2.8 Flowering time

In the development of all woody plants from seed, there is a juvenile phase, lasting 3–7 years in apple (Visser, 1964), during which flowering does not occur and cannot be induced under normal conditions (Hackett, 1985). In the fruit industry, it is important to accelerate flowering by reducing the juvenile phase of the trees after planting in order to facilitate the earliest possible production of fruit. In fruit breeding, various practical techniques have been considered to accelerate the flowering of seedlings. The basic idea is to grow the seedling rapidly from the germination stage to the flowering stage (Visser, 1964; Zimmerman, 1971; Aldwinckle, 1975). In apple, grafting the seedling onto dwarfing rootstocks, such as M9 and M27, will usually bring earlier flowering by 1 or 2 years (Visser, 1973). Using some of these techniques, Zimmerman (1971) produced the first flowering in crabapple seedlings within 13 months, and Aldwinckle (1975) obtained flowering 16–20 months after germination of seeds of apple cultivars at above node 120 from the base of the plants. Yao *et al.* (1999), by incorporating techniques used for reducing the juvenile period into the

containment greenhouse management practice, were able to promote rapid flowering, after 2 years, of the transgenic Royal Gala line, for subsequent analysis of the transgene expression. However, under normal conditions, it would be difficult to reduce the juvenile phase of an apple seedling to less than 4 years even if they are grafted on dwarfing rootstocks. Significant correlations have been found between the length of the juvenile phase and parent characteristics, such as growth rate and the length of the vegetative phase (Lavi *et al.*, 1992).

The most striking advances of the genetic control of flowering times come from studies in *Arabidopsis* (Levy and Dean, 1998; Pineiro and Coupland, 1998). Several genes that control flowering time have been isolated, namely *LEAFY* (*LFY*) (Weigel *et al.*, 1992), *APETALA1* (*API*) (Mandel *et al.*, 1992), *TERMINAL FLOWER 1* (*TFL1*) (Ohshima *et al.*, 1997), and *FLOWERING LOCUS* (*FT*) (Kardailsky *et al.*, 1999). In transgenic *Arabidopsis*, overexpression of *LFY*, *API* or *FT* shortens the juvenile phase and causes early flowering (Mandel *et al.*, 1992; Weigel and Nilsson, 1995; Kardailsky *et al.*, 1999; Kobayashi *et al.*, 1999), whereas *TFL1* overexpression causes late flowering (Ratcliffe *et al.*, 1999). *TFL1* plays a key role in the maintenance of the inflorescence meristem by preventing the expression of *LFY* and *API* in the shoot apical meristem (Liljegren *et al.*, 1999). Apple orthologs of several of these genes, such as *AFL1*, *AFL2*, *MdAPI* (*MdMADS5*), and *MdTFL1* have been isolated and characterized (Kotada *et al.*, 2000, 2002; Kotada and Wada, 2005). Kotada *et al.* (2006) were able to reduce the juvenile period in apple by silencing the *MdTFL1* gene. Indeed, depending on the copy number of the *MdTFL1* antisense gene integrated in the apple genome, the first flower appeared between 8 and 25 months after transfer of the transgenic lines in the greenhouse, whereas the first flower in the nontransformed control appeared 69 months after transfer in the greenhouse. Most flowers of the transgenic lines had functional reproductive organs, resulting in normal fruit that contained several seeds. The pollen and the seed of these plants are viable.

An alternative approach to the silencing of the *MdTFL1* gene is to induce flowering by the overexpression of genes involved in the formation

of floral meristems, such as the *LFY*, *API*, or *FT* genes. Hanke *et al.* (2007a) chose this approach and transformed the apple cultivars Pinova with the *BpMADS4* gene of silver birch, which is similar to the *FT* gene. Some apple transgenic lines, constitutively expressing this gene, showed development of flowers *in vitro*. For example, some transgenic lines showed a solitary flower *in vitro* 13 weeks after transformation (Hanke *et al.*, 2007a). Most of these flowers appeared morphologically normal, but some were abnormal (Hanke *et al.*, 2007a).

The further use of these transgenic lines should be useful in breeding, cultivars production, and basic research, for example, molecular and physiology studies on the effects of genes in fruit development and disease resistance.

2.2.9 Self-fertility

Fruit production in many tree fruit crops is dependent on cross-pollination between cultivars. This is due to the existence of a self-incompatibility (SI) mechanism, which is a widespread intraspecific system to prevent self-fertilization that is controlled by a single *S*-locus. Cross-pollination between compatible cultivars depends on insects as pollen vectors during flowering, and their activity is impaired by inclement weather. Suboptimal pollination efficiencies are one of the factors contributing to low fruit yields that may occur in some years in commercial orchards (Goldway *et al.*, 1999). There is a strong interest in the self-fertile character in many fruit and nut tree crops because self-pollination could ensure more consistently high production compared to cross-pollination. This has been apparent in sweet cherry and almond, where dysfunctional *SI* genes have been obtained through mutagenesis and interspecific crosses. Although the severity of the *SI* reaction varies between cultivars and pollination conditions, truly self-fertile apple cultivars are commercially nonexistent (Broothaerts *et al.*, 2004a). Moreover, because high crop yields often create lower quality fruit and stimulate a biennial bearing tendency, it is unclear whether self-fertility would be beneficial for apple production. Broothaerts *et al.* (2004a) addressed this concern by silencing the *SI* mechanism in apple. Controlled self- and cross-pollination of the

flowers of the transgenic Elstar and nontransgenic apple trees over a 3-year period showed that transgenic lines produced normal levels of fruit and seeds after selfing. In contrast, the controls produced much less fruit following self-pollination compared to cross-pollination (Broothaerts *et al.*, 2004a). Further work should be undertaken to study the behavior of the transgenic trees under natural growth conditions to find out to what extent self-fertility affects crop yield under various environmental conditions. The self-fertile trees may also be used as a tool to study inbreeding depression, or for the development of homozygous breeding lines.

2.2.10 Selectable markers

Selectable marker genes are widely used for the efficient transformation of crop plants. In most cases, selection is based on antibiotic or herbicide resistance. These marker genes are preferred because they tend to be most efficient (e.g., in apple up to 80% transformation rate with the *nptII* gene for kanamycin resistance Table 2). Due to concerns about acceptability of antibiotic resistance genes in fruit cultivars, considerable effort is being put into developing a suite of strategies (site-specific recombination, homologous recombination, transposition, and co-transformation) to eliminate the marker gene from the nuclear or chloroplast genome after selection (Miki and McHugh, 2004). Current efforts are emphasizing systems in which the marker genes are eliminated efficiently soon after transformation (Schaart *et al.*, 2004) by using the cre-lox system. Schaart *et al.* (2004) were able to produce some transgenic Elstar containing no selectable marker. However, these methods are tedious and total elimination may be questioned. Alternatively, transgenic apple can be produced by the use of marker genes that do not rely on antibiotic or herbicide resistance but instead promote regeneration after transformation. Examples are (Table 2) phosphomannose isomerase (Flachowsky *et al.*, 2004; Zhu *et al.*, 2004; Degenhardt *et al.*, 2006; Szankowski and Degenhardt, 2007) and Vr-ERE (Chevreau *et al.*, 2007). Only Degenhardt *et al.* (2006) reported the regeneration of transgenic apple lines using the *pmi* gene as selectable marker

with a rate of transformation from 1% to 24%. The other report shows the expression of the reporter gene in the transformed leaves but they did not regenerate into plants. Other methods based on the transformation of apple without any selectable marker have also been reported (Malnoy *et al.*, 2007a). Here, genetically modified apples are produced by *Agrobacterium* inoculation followed by regeneration of shoots without the use of a selectable agent. This produces many plants, the majority of which are nontransgenic. However, depending on the regeneration and gene transfer frequencies, some plantlets are transgenic and have to be identified by PCR screening. A prerequisite is a regeneration/transformation protocol of high efficiency. So far, this method has been limited to model plants and few specific crop cultivars, for example, in potato. Due to the very high efficiency of transformation of the apple genotypes Galaxy and M.26, Malnoy *et al.* (2007a) have been developing this technique in apple. They reported regeneration via this procedure for both genotypes with an efficiency of transformation close to 12% for Galaxy and 25% for M.26.

These methods are generally of lower efficiency than that achieved using *nptII*, but are promising for production of marker-free cultivars for commercial use.

2.3 Stability of Inheritance of the Transgene, Yield, and Quality

The technology for efficient production of transformed apple lines has now been developed, and transformed plants and fruiting trees can be obtained relatively quickly. Some transformed lines of apple have shown an increase in resistance to fire blight in field trials, and the fruit of these lines has shown no difference in quality, size, or yield compared to the control (Aldwinckle *et al.*, 2003b). Ruhmann *et al.* (2006) showed some similar results that the expression of the *S. synthase* gene does not affect the quality of the fruit.

With the respect to the release of transgenic woody plants the stability of the integrated transgenes and their long-term expression is one of the main objectives in monitoring and risk assessment of genetically engineered plants. Stable integration and expression of transgenes is important for fruit trees, which have an

exceptionally long productive life compared with annual crops. Several laboratories have studied the stability of expression of transgenes in transgenic apple. James *et al.* (1995, 1996) showed the stable expression and Mendelian expression of transgenes in transgenic Greensleeves. They showed a 1:1 segregation of the *nos* gene in the R₁ transgenic apple progeny. In addition, they reported the evidence of stable expression of both *nos* and the cotransformed gene *nptII* in the fruit flesh of the apple fruit some 7 years after the initial transformation. Briviba *et al.* (2004) reported stable expression of the *S. synthase* and the *bar* gene in apple 3.5 years after transformation, in all the transgenic lines except one. In contrast, Reim and Hanke (2004) reported that in 34% of the transgenic lines examined that the transgene, the selectable marker, or either gene was not detected, after several years in greenhouse.

2.4 Regulatory Measures Adopted

Like other genetically engineered (GE) crops in the United States, GE apple is regulated by the Institutional Biosafety Committee (IBC), the Animal and Plant Health Inspection Service (APHIS) of USDA, the Food and Drug Administration (FDA), and the Environmental Protection Agency (EPA). There is no internationally accepted regulatory protocol for field trial or commercialization of apple.

The IBC is an internal responsibility of each research institution. It monitors potentially hazardous biological research and ensures compliance with biological safety procedures. APHIS must determine whether a GE plant cultivar is likely to become a pest, i.e., to have a negative agricultural or environmental effect. APHIS regulates the import, transportation, and field testing of GE plants through notification and permitting procedures. For the commercialization of GE plants, APHIS requires extensive data on the introduced gene construct, effects on plant biology, and effects on the ecosystem, including spread of the gene to crops or wild relatives. After the GE crop is on the market, APHIS has the authority to halt its sale, if there is evidence that the plant is becoming a pest. FDA determines the safety of foods or food ingredients. EPA regulates GE plants that are engineered for pest resistance.

A major concern for apple growers is that nonscience-based tactics would be used by nongovernment organizations (NGOs) to raise public concern about GE cultivars, and by extension about apples in general. Such concerns include the possible spread of antibiotic resistance, used for the selection of GE cultivars, to pathogens of humans and livestock; the use of genes from other organisms, especially animals; and the unstable insertion of the CaMV 35S promoter. The spread of antibiotic resistance persists as a concern despite a panel of international experts concluding that the probability of gene transfer to gut bacteria is extremely remote (WHO, Joint FAO/WHO Expert Consultation on Food Derived from Biotechnology; topic Gene Transfer: Mechanisms and Food Safety Risks, http://www.who.int/fst/Gmfood/consultation_May2000/biotech_00_14.pdf). To alleviate some of these concerns, techniques avoiding use of selectable markers during the process of transformation, or techniques eliminating such markers after transformation, have been developed and have begun to be used for the production of a new generation of GE crops.

The testing and release of GE organisms, especially GE plants, is tightly regulated internationally with the intention of preventing any negative effects on the environment or human health. However, these regulations are based on transgenic organisms and do not discriminate between transgenic plants and intragenic plants, although we believe that there are fundamental differences between them. Although transgenesis and intragenesis both use the same GE techniques namely the introduction of one or more genes and their promoters into a plant, intragenesis involves only genes from the species itself or from an interfertile relative. Such intragenes could be transferred by traditional breeding techniques. If the current GE regulations, which are mainly based on the process of transferring transgenes, continue to fail to differentiate between intragenic and transgenic plants, the use of intragenesis could be unintentionally hampered. Only Canada now has a product-based rather than a process-based regulation system, and therefore has the legal possibility to control intragenic plants less strictly than transgenic plants. Nielsen (2003) differentiated between intragenic and transgenic plants, and Schouten *et al.* (2006) argue that this

type of GE plant (termed cisgenic in their paper) should be treated differently under GE regulations.

In the case of an intragenic plant, the gene of interest has been present in the gene pool of the species and its interfertile relatives for evolutionary time periods. Therefore intragenesis does not alter the gene pool of the recipient species. An example is the introduction of the apple scab resistance gene *Vf* from a wild species into the domestic apple, which began as early as the 1950s (Schmidt and van de Weg, 2005). Despite more than 50 years of traditional breeding programs, the new apple cultivars carrying this gene have yet to acquire the same fruit quality in terms of taste and texture as the popular commercial susceptible cultivars, because of linkage drag. As the *Vf* gene has recently been cloned (Belfanti *et al.*, 2004; Malnoy *et al.*, 2007d), its transfer into elite cultivars using intragenesis should lead to more useful results in a considerably shorter time. However, whether this technique will develop into a powerful new tool strongly depends on several factors, including especially how intragenic plants are treated by existing legal frameworks, and the consumer acceptance of such products. Although consumer acceptance is beyond the control of lawmakers and regulators, it would be sensible to regulate intragenic plants differently than transgenic plants. Self-evidently, intragenic plants should still be tested to confirm that they contain only the intended changes and no foreign genes, such as a backbone gene from a plasmid.

3. FUTURE ROAD MAP

Much methodological progress has been made in the field of genetic engineering of apple in the last 10 years, and this has already resulted in production of new plant genetic material, which is currently being evaluated. However, progress is still needed in order to adapt techniques to a larger range of varieties and rootstocks, and to develop selection techniques, which avoid the need for antibiotic resistance transgenes. In the coming years, more diverse horticultural traits will certainly be amenable to genetic engineering, with increased knowledge of the genetic mechanisms underlying the traits of interest. The recent announcement of the funded project to sequence the apple genome will soon result in availability

of the sequence of many useful apple genes (R. Velasco, personal communication). However, before transformed apple can be commercialized, several important issues need to be addressed. Risk assessment studies must be thoroughly conducted to evaluate the potential toxicity or allergenicity of the transformed products and the environmental consequences of an eventual gene flow to natural populations of wild *Malus*. More research efforts must be devoted to search for regulatory sequences enabling targeted and controlled expression of the genes, and stability of expression of the gene throughout the tree life should be ensured. Practical use of transformed apple varieties will not be possible without general public acceptance.

One of the recurring themes of the debates concerning the application of genetic transformation technology has been the role of intellectual property rights (IPR). This term covers both the content of patents and the confidential expertise usually related to methodology and referred to as "Trade secrets" (Dunwell, 2005). Although few of the patents of this area have any real commercial value, there are small number of key patents that restrict the "freedom to operate" of new companies seeking to exploit the methods. Over the last 20 years, these restrictions have forced extensive cross-licensing between ag-biotech companies and have been one of the driving forces behind the consolidation of these companies, although, such issues are often considered of a little interest to the academic scientists working in the public sector. During the period since the production of the first transformed plants, a wide diversity of patents have been sought on all aspects of the process, ranging the underlying tissue culture methods through the means of introducing the heterologous DNA, and also the composition of the DNA construct so introduced (Kesan, 2000).

Recent advance that may circumvent the IPR limitation to *Agrobacterium* technology is the development of gene transfer techniques using other bacteria, such as *Sinorhizobium* (Broothaerts *et al.*, 2005). It is claimed that these methods may offer an open source alternative to the established transformation technologies.

1. INTRODUCTION

Pears are fruit trees belonging to the genus *Pyrus*, and are native to temperate Europe and to temperate and subtropical Asia. Pears are now cultivated in all temperate regions of the world. Modern cultivars of the European pear are considered by many people of western origin to be one of the most delectable of tree fruits, combining a buttery juicy texture with rich flavor and aroma. The pears of China, Korea, Japan, and elsewhere in eastern Asia are preferred there for their crisp texture and sweet flavor.

1.1 History, Origin, and Distribution

The genus *Pyrus* belongs to the apple subfamily *Maloideae* of the rose family *Rosaceae*, and contains eight widely recognized primary species, all indigenous to Europe, temperate Asia, and the mountainous areas of northwestern Africa (Westwood, 1982). The genus probably evolved during the Tertiary period in the foothills of the Tian Shan mountains in Xinjiang Province in western China, and spread eastward throughout temperate and subtropical Asia and westward throughout Europe, with isolation and adaptation leading to speciation. Vavilov (1951) identified

three centers of diversity for the genus: China, Central Asia, and the Near East/Asia Minor. The Near Eastern center, and specifically the Caucasus Mountains, is believed to be the center of origin of domesticated forms of the European pear, *Pyrus communis*.

The earliest written record of pear culture in Europe is that of Homer, who wrote in Greece about 1000 BC that pears were one of the “gifts of the gods” (Hedrick *et al.*, 1921). By the time of Theophrastus (371–286 BC), pear culture was well established in Greece and cultivars with distinct names were propagated by grafting and cuttings. Great strides in selection of the buttery fleshed cultivars, including “Beurré Bosc” and “Doyenné du Comice”, were made in the 18th century Belgium and France. Selection of edible fruit types from wild populations in China began about 3300 years ago, and pears have been cultivated in China for more than 2000 years.

1.2 Botanical Description

The pear genus (*Pyrus L.*) can be divided into two sections. The *Pashia* Koehne section includes the species of Eastern Asia and includes the small-fruited species of *P. armenicifolia* Yu, *P. betulifolia* Bunge, *P. calleryana* Decne, *P. kawakamii* Hayata,

and *P. xerophila* Yu, and the medium- to large-fruited *P. pyrifolia* Burm., *P. pashia* D. Don., and *P. ussuriensis* Maxim. There are several naturally occurring interspecific hybrid taxa, including *P. × bretschneideri* Rehd. (probably, a hybrid of *P. pyrifolia* and *P. ussuriensis*), which includes many important cultivars, and *P. sinkiangensis* Yu, a complex hybrid group of cultivars thought to be derived from *P. ussuriensis*, *P. × bretschneideri*, and *P. communis*. Section *Pyrus* includes the species of the secondary diversity centers of Central Asia, *P. salicifolia* Pall. and *P. regeli* Rehd., of the circum-Mediterranean, *P. amygdaliformis* Vill., *P. elaeagrifolia* Pall., *P. syrica* Boiss., and *P. cossonii* Redh., and of Europe, *P. caucasica* Fed., *P. nivalis* Jacq., and *P. pyrastrer* Burgsd., and the cultivated species, *P. communis* L.

The plants of all species are trees or large shrubs, and are deciduous except for *P. kawakamii*, which is semi-evergreen and is native to Taiwan and Southeast Asia. Climatic and edaphic adaptation is wide, with most species occurring naturally in temperate mixed hardwood forests, at altitudes up to 2200 m above sea level. Tree habit can be strongly upright to spreading, reaching a height of more than 24 m and trunk diameter of 1 m or more. The pome fruits vary considerably in size, but have juicy flesh, with variable amounts of stone cells, especially in the East Asian species. Fruit shape varies from obovoid or subglobose to pyriform in *P. communis*, *P. × bretschneideri*, and *P. sinkiangensis* Yu, obovoid or round in *P. pyrifolia* and *P. ussuriensis*, to round in *P. calleryana*, and *P. betulifolia*. Fruit skin color in *P. communis*, *P. pyrifolia*, and *P. × bretschneideri* can be yellow to light green at maturity, or covered with a tan to brown russet. Flesh texture of the latter two Asian species is crisp, while that of *P. ussuriensis* and *P. sinkiangensis* tends to be soft. Most existing cultivars of *P. communis* have melting, buttery flesh, but cooking cultivars with hard, coarse texture exist and, in fact, were more common prior to the 1700s.

The genus has a basic chromosome number of 17, and may have arisen as an amphidiploid of two primitive forms of the *Prunoideae* ($x = 8$) and *Spiraeoideae* ($x = 9$) (Bell *et al.*, 1996). All species of *Pyrus* that have been examined are diploid ($2n = 34$, $x = 17$), but occasional triploids such as “Beurre Amanlis”, “Cure”, “Minister Dr. Lucas” and “Buerre Bedford” and tetraploids

such as “Parberton Bartlett”, “Double Williams”, “Improved Fertility”, “Large Winter Nelis”, and “Trevu Tetra” can be found. Diploid DNA content is approximately 0.55–0.63 pg (picogram), depending on species (Arumuganathan and Earle, 1991; Dickson *et al.*, 1992), with total map length estimated at approximately 950 cM (Yamamoto *et al.*, 2002). The chloroplast DNA is circular and 156 kb in length (Katayama and Uematsu, 2003).

1.3 Economic Importance

Pears rank second to apples in the amount of worldwide production of deciduous tree fruit species. Pears are grown in 63 countries throughout the temperate and subtropical regions of the world. Cultivars of *P. communis* are the main edible pears in Europe, the Middle East, western Asia, North America, and mountainous areas of Central America. The snow pear, *P. nivalis* Jacq., is also grown to a limited extent in France and the United Kingdom for making the alcoholic beverage called perry. In Asia, *P. pyrifolia* is the main cultivated species in central and southern China, Korea, Japan, Taiwan, and other countries of Southeast Asia. In northern China, *P. ussuriensis*, *P. × bretschneideri*, and *P. sinkiangensis* are grown. Selections of *P. pashia* are cultivated in southern China and South Asia. Hybrids of *P. pyrifolia* and *P. communis* are grown in southern temperate and subtropical regions of North and South America, and in Egypt where chilling hours to overcome bud dormancy fall below 800 h. Species used for ornamental purposes include the small-fruited *P. calleryana* Decne., *P. fauriei* Schneid., *P. betulifolia* Bunge, *P. salicifolia* Pall., and *P. kawakamii* Hayata. Seedlings and clonal selections of *P. communis* are generally used as rootstocks for European pear scion cultivars, while *P. betulifolia*, *P. calleryana*, *P. pyrifolia*, *P. ussuriensis*, and *P. × bretschneideri*, are used as rootstocks in Asia, and *P. pyrastrer* Burgsd., *P. amygdaliformis* Vill., and *P. elaeagrifolia* Pall. are occasionally used in Asia Minor and Central Asia (Lombard and Westwood, 1987). Quince (*Cydonia oblonga* L.) is also used as a rootstock for European pears in regions where lack of cold hardiness is not a limiting factor.

The remarkable increase in world pear production from 1990 to 2005 was mainly due to the growth of area harvested which increased

from 1.1 million ha to 1.9 million ha, with much of the reported increase due to China, now at 1.2 million ha. In Europe, there was a strong expansion in pear growing in the 1980s, followed by a small reduction to 220 000 ha. The other major producing regions include South Africa (46 000 ha), North America (40 000 ha), South America (38 000 ha), and Oceania (10 000 ha).

Production in all countries in 2005 totaled 19.5 million metric tons (mt) (FAOSTAT, 2007) with an annual growth rate of nearly 5% in the last decade. More than 65% of the world production is concentrated in Asia, with Southern Europe ranking second with a 12% share of total world production. China produced some 11.5 mt. The rate of change in production in China from 1990 to 2005 was 300%. Other major producing countries were Italy (926 540 mt), the United States (747 250 mt), Spain (671 000 mt), Argentina (535 420 mt), and Turkey (450 000 mt). In Europe, pear production totals ca. 3.5 mt, with 87% of this production in six countries: Italy 28%, Spain 22%, Germany 14%, France 9%, Belgium 8% and The Netherlands 6% (USDA/FAS, 2006).

Economic usage of *Pyrus* species has been reviewed by Bell *et al.* (1996). Most of the fruit crop is utilized as fresh fruit, but significant amounts are processed and marketed as canned pears, dried fruit, puree, blended juices, or pure nectar, and alcoholic beverages such as perry, and still and sparkling pear wine. As noted, several east and mid-Asian species, especially the callery pear, *P. calleryana*, are widely used as ornamentals.

On the basis of 100 g of the edible portion, including skin, European pears provide 58 kcal of energy (USDA, 2004). They consist of 78–86% water, 1.6–3.6% crude cellulose, 0.4 g of protein, 0.12 g fat, 15.5 g of total carbohydrate, 9.8 g of total sugars, two-thirds of which are fructose, and 3.1 g of fiber. Of the major mineral nutrients, there are 8 mg of calcium, 11 mg of phosphorus, 0.3 g of iron, 2 mg of sodium, and 130 mg of potassium. There are 20 IU of vitamin A, 0.02 mg of thiamine, 0.04 mg of riboflavin, 0.1 mg of niacin, and 4 mg of ascorbic acid (vitamin C). Of the major temperate tree fruits, pears are highest in fiber, average to low in mineral elements, and lowest in vitamin A. For the remaining vitamins, pears rank low to average. Values for *P. pyrifolia* are similar. The oxygen radical absorbance capacity of pears ranks just below tomatoes, less than 10% of the amount

in strawberry, and is also only moderate for the total phenol antioxidant index.

1.4 Traditional Breeding

Pear culture in Europe dates from ancient Greece and Rome, and led to a very great diversity of local cultivars throughout Europe. European pear breeding reached its “golden age” between 1750 and 1850 in Belgium, France, and England (Bell *et al.*, 1996). Selection was performed among open-pollinated seedlings of common cultivars of *P. communis*. Several cultivars released during this period still constitute the basis of the current European pear production: “Conference” (England, 1885), “Williams Bon Chrétien” (England, 1796), “Abbé Fétel” (France, 1866), “Docteur Jules Guyot” (France, 1870), “Doyenné du Comice” (France, 1849) (Doré and Varoquaux, 2006). Controlled hybridization was probably used by pear breeders since the second half of the 19th century. Documents from the Brno monastery indicate that Gregor Mendel himself studied pear taste and ripening time, and performed controlled hybridization between several pear varieties (Vavra and Orel, 1971).

In Asia, the consumption of European pears is low, and most of the pear production is from Asiatic species (*P. pyrifolia*, *P. ussuriensis*, *P. × bretschneideri*) and their hybrids. Until the 20th century, most of the cultivars grown in this part of the world were chance seedlings. Pear breeding programs in Asia have been recorded since 1915 in Japan, 1920 in Korea, and 1956 in China (Bell *et al.*, 1996).

1.4.1 Modern breeding objectives

Pear trees are grown on rootstocks, belonging to the genera *Pyrus* and *Cydonia*, and different breeding aims are documented for scion and rootstock cultivars. There are numerous objectives of European and Asian pear scion genetic improvement. Until the middle of the 20th century, breeding was mainly focused on improving tree vigor, productivity, and fruit appearance. However, increasing importance of economics in fruit production, evolution of marketing, and necessity of environmentally friendly production systems

extended breeding objectives to the characteristics including tolerance or resistance to pest and diseases, adaptability to environmental factors, extension of the harvesting period, extension of storage and shelf life, and taste and nutritional characteristics (Bellini and Nin, 2002).

Resistance to pests and diseases is a major objective of most pear breeding programs in Europe and northern America. Fire blight, caused by the bacterium *Erwinia amylovora*, is considered the most devastating disease in pear. Two important breeding programs have already released tolerant or resistant varieties from Harrow (Canada) and Kearneysville (USA) (Lespinasse and Aldwinckle, 2000). Resistance to pear psylla (*Cacopsylla pyricola*), which is the insect vector of pear decline phytoplasma, pear scab (*Venturia pirina*), and powdery mildew (*Podosphaera leucotricha*), is also sought in European pears. Resistance to black spot caused by *Alternaria alternata* and resistance to pear scab caused by *Venturia nashicola* are important for Asian pear breeding. Adaptability to environmental factors is focused mostly on cold hardiness in northern parts of Europe, Asia, and America, but also includes adaptation to hot and humid tropical climates in countries such as India and Taiwan. Growth habit modification goals are generally toward compact size and rapid cropping. In France, particular attention is given to tree bearing and branching to facilitate a modern orchard management system with reduced labor cost (Costes *et al.*, 2004). Many pear scion breeding programs share the common aim of extension of the harvest season, either for early ripening pear or for late ripening “winter” pear with long storage ability. Improvement of fruit quality is a complex objective, which includes fruit size, appearance, flesh quality, storage ability, nutritional value, and adaptation to various industrial uses (canning, baby food). Attributes of good quality differ between European and Asian pears, and some breeding programs now attempt to create completely new pear types by hybridizing between European and Asian pears (White and Brewer, 2002).

European pears are grown on clonal rootstocks belonging either to *P. communis* or to *C. oblonga* (quince rootstocks). *P. communis* rootstocks generally exhibit good graft compatibility, tolerance to fire blight and iron chlorosis, and average fruit size and ability to propagate, but they are often

too vigorous for intensive pear orchards. Quince rootstocks confer dwarfing-induced vigor, good fruit size, and good ability to propagate but they can lead to graft incompatibility and susceptibility to iron chlorosis. Asian pears are grown on seedlings of *P. communis*, *P. pyrifolia*, *P. pashia*, *P. calleryana*, *P. ussuriensis*, and *P. betulaefolia* (Wertheim, 1998). The principal goal of pear rootstock breeding today is to combine dwarfing-induced vigor with good compatibility and ability to propagate. Traits of particular importance for pear rootstocks also include tolerance to drought, waterlogging, and lime-induced iron chlorosis (Wertheim and Webster, 2005). Incompatibility of many pear scion cultivars with quince rootstocks led modern pear rootstock breeding programs to investigate the use of *Pyrus* species. One of the main drawbacks in developing *Pyrus* rootstocks is the rare coincidence of dwarfing potential and ease of propagation (Bell *et al.*, 1996).

1.4.2 Tools and strategies

Fruit tree breeding methods generally involve three major steps: creation of genetic variation, selection of elite material, and extended trials of promising preselections before market release (Schmidt and van de Weg, 2005). Crossing is still by far the most widely used method of creation of genetic variability for pear. The genetic pool available for the pear breeder is wide. Most species of *Pyrus* are diploid ($2n = 34$; $x = 17$) and no significant interspecific cross-incompatibility is known to exist. Crossing programs rely on the availability of appropriate genetic resources, which can comprise recent breeding selections, old and new cultivars, and various species of the genus *Pyrus*.

Mutation induction, although efficient for some characteristics such as skin color, compact growth, or tetraploidy, has never played a major role in pear breeding. The occurrence of chimera, which is often unstable, is one of the major obstacles to the use of spontaneous or induced mutations for pear breeding (Chevreau *et al.*, 1989a, b). Recently, *in vitro* systems for pear mutation breeding have been developed to decrease the risk of obtaining chimeric plants, either by using adventitious regeneration or by applying rapid cycles of micropropagation to separate

mutated from nonmutated sectors (Predieri and Zimmerman, 2001).

The contribution of *in vitro* methods to create novel genetic variability in pear has advanced considerably during the two last decades. Haploidization via *in situ* parthenogenesis induced by irradiated pollen and *in vitro* rescue of the haploid plantlets have been successfully developed for pear (Bouvier *et al.*, 1993). Techniques of adventitious bud regeneration from *in vitro* leaves have been developed for several genotypes of European and Asian pears and for quince. So far, applications of these techniques for the induction of somaclonal variation have been very limited. The occurrence of somaclonal variation has been demonstrated for fire blight resistance and iron-chlorosis tolerance, albeit at low frequency (Chevreau and Bell, 2005). Protoplast technology has also been applied to pear since 1986 by Ochatt and Caso (1986). However, somatic hybridization between *Pyrus* and an incompatible genus, *Prunus*, has been reported only once (Ochatt *et al.*, 1989) and has not been confirmed.

1.5 Limitations of Conventional Breeding and Rationale for Transgenic Breeding

1.5.1 Conventional breeding accomplishments

Many new European pear scion cultivars have been developed from hybridization programs and released within the last 20 years with major improvements in the quality, storage, and shelf life of early season pears, as well as in late season pears. Important progress has also been made in the field of disease resistance, particularly concerning fire blight. Countries with the highest number of pear scion releases since 1990 have been the United States, Germany, France, Russia, and Italy. However, very few of these novel cultivars have the potential to replace the classical pear cultivars whose agronomic and commercial limits are already well known and which have gained a solid market share (Bellini and Nin, 2002). Successes of induced mutagenesis for pear improvement are still limited. Three mutants of Asian pear (“Gold Nijisseiki”, “Kotobuki Shinsui” and “Osa Gold”) have been released. They were obtained after chronic γ -irradiation of plants and were selected

for increased resistance to black spot disease, caused by *A. alternata* (Yoshioka *et al.*, 1998).

Rootstock breeding programs are considerably longer term than scion breeding programs, because no reliable laboratory technique is available so far to preselect for vigor induction and compatibility before testing rootstock/scion combinations in the orchard. Despite hybridization programs in several countries and release of several new rootstocks, there is still a lack of compatible dwarfing pear rootstocks of *Pyrus* type, combining a good propagation ability with disease resistance, and adaptation to difficult environmental conditions (cold, drought, or lime-induced chlorosis) (Wertheim, 2002).

1.5.2 Progress toward marker-assisted selection

One of the main limiting steps toward pear genetic improvement by hybridization is the length of the juvenile period. The majority of pear seedlings flower between the 5th and the 7th year after crossing. No reliable correlation is known between fruit characteristics and vegetative traits. Apart from a few disease resistance traits from which preselection through seedling inoculation is efficient (scab, fire blight, psylla), selection can only start when the trees start cropping. In conventional pear breeding, only one to five seedlings are retained per 1000 per generation, therefore the cost of orchard management for pear hybrid selection is very high.

Important efforts have been devoted to the development of various types of molecular markers for pear. These include isozymes, restriction fragment length polymorphism (RFLP) markers of mitochondrial DNA, random amplified polymorphic DNA (RAPD), amplified fragment length polymorphism (AFLP), simple sequence repeat (SSR), and selectively amplified microsatellite polymorphic loci (SAMPL). But so far they have been used mostly for cultivar identification or phylogenetic studies. Integration of molecular markers into pear genetic studies and breeding requires additional knowledge about the linkage between molecular markers and the desired traits. Three traits have been linked to molecular markers in Asian pears: a major gene for resistance to black spot disease, the *S*

locus of self-incompatibility, and two ACC (1-Aminocyclopropane-1-carboxylate) synthase genes (Chevreau and Bell, 2005). Recently, genetic linkage maps of both European and Asian pears have been constructed based on an interspecific cross (Yamamoto *et al.*, 2002). Position of the resistance allele for pear scab (*Vn*) and the susceptible allele for black spot (*A*) were mapped in different linkage groups in Asian pear (Iketani *et al.*, 2001), as well as the first quantitative trait loci (QTLs) for fire blight resistance in European pear (Dondini *et al.*, 2004). The high degree of conservation between apple and pear genomes should also speed up the localization of important agronomical traits. Recently, the pear scab resistance gene, *Vnk*, from the Japanese pear “Kinchaku” was located on the same linkage group as the apple scab resistance gene *Vf*, but in a different genomic region (Terakami *et al.*, 2006). Despite this progress, marker-assisted selection (MAS) will take place only very gradually in the pear hybrid selection process.

1.5.3 Rationale for transgenic pear breeding

Marketing of pears both within and among nations is characterized by a ceiling on the number of cultivars. In Europe, less than 10 cultivars constitute 75% of the pear production (Deckers and Schoofs, 2005). Over 80% of the North American pear production can be accounted for by three cultivars (Seavert, 2005). In China, three cultivars account for about 65% of the national production (Saito *et al.*, 2005). Both producers and consumers prefer the old traditional cultivars, which are unique and clearly recognized. Therefore, acceptance of new hybrid cultivars is very slow.

In this context, gene transfer offers pear breeders new tools to directly improve existing elite cultivars without changing their main recognizable characteristics. An improvement in any of these few important cultivars should necessarily have a significant impact on production. However, one should not imagine that gene transfer is a simple process that will speed up the selection of new cultivars. After the selection of a promising transgenic clone, much time is needed to test the stability of the expression of the transgene

and of the associated desired new trait, to check the maintenance of the other traits of the original cultivar, and to establish the safety of the fruits produced. Also at the moment, the European public does not seem to accept genetically engineered (GE) processed food, and might be even more reluctant to accept GE fresh products, such as fruits. However, acceptance of transgenic pear cultivars may be easier in other parts of the world, especially the United States and Canada. GE pear rootstocks should be much more easily commercialized, as the risk of dissemination of the transgene through pollen flow is absent, as well as the concerns about food safety.

Even though the direct use of gene transfer for pear breeding seems a long-term goal, the various possibilities offered by gene transfer to overexpress or silence a precise gene constitutes a unique tool for the progress of genetic knowledge of this species. With the increased speed of gene discovery in fruit species, gene transfer will become a necessary tool to demonstrate the function of these genes. Finally, combination of conventional breeding aided by molecular markers and transformation techniques to alter expression of *Pyrus* genes rather than using genes from other organisms will also offer a very attractive approach.

2. DEVELOPMENT OF TRANSGENIC PEARS

2.1 Development of a Pear Transformation Procedure

Development of an effective system for gene transfer in pear depends largely on the availability of tissue culture techniques that permit efficient DNA delivery, regeneration of shoots, selection of transformants, and propagation of transformed plants. In many instances, the lack of efficient regeneration systems is the major limiting factor preventing the development of gene transfer technologies for perennial crops (Dandekar, 1992).

Development of a genetic manipulation system for the production of transformed fruit trees greatly depends on the establishment of a reliable and effective regeneration and transformation system. Adventitious shoot formation from leaf

explants has been reported for a limited number of mostly commercial genotypes, including *P. communis* cultivars (Chevreau *et al.*, 1989b, 1997; Chevreau and Leblay, 1993; Predieri *et al.*, 1989; Abu-Qaoud *et al.*, 1991; Leblay *et al.*, 1991), *P. pyrifolia* cultivars (Lane *et al.*, 1998), *P. syriaca* Boiss. genotypes (Shibli *et al.*, 2000), wild pear *P. communis* var. *pyraster* L. (Caboni *et al.*, 1999), and quince rootstocks (Dolcet-Sanjuan *et al.*, 1991; Baker and Bhatia, 1993). In all cases, leaves from *in vitro* grown plants have been used as explants and have been exposed to a sequence of dark (2–4 weeks) and light exposure. The optimum culture conditions for adventitious regeneration are summarized in Table 1. These techniques involve a very limited callus phase at the site of wounding, and bud regeneration occurs in 3–6 weeks.

Although sufficient regeneration levels were achieved in some of these genotypes, the regeneration of transformed plants remains a difficult task and seems to be strongly genotype dependent.

The first successful gene transfer in the pear was in 1996 (Mourgues *et al.*, 1996) some years after the first transformation in the apple (James *et al.*, 1989), and to date, several transgenes (*attacin*, *rolC*, and *rolB*) have been introduced into pear cultivars such as Passe Crassane (Reynoird *et al.*, 1999a), Beurre Bosc (Bell *et al.*, 1999), and *Pyrus* rootstocks. Although transformation of several pear cultivars has been reported (Table 2), the transformation rates were generally 1–4% with the exception of an impressive efficiency of up to 42% in Conference and up to 59% in Burakovka (Lebedev *et al.*, 2002a, b). In most of these cases, obtaining transformed shoots took at least 6 months, whereas Gao *et al.* (2002) obtained transformed shoots within 1.5 months due to the use of juvenile explants. Using cotyledons, the authors concluded that transformants of woody fruit trees can be produced quickly when no specific cultivar is considered. The method of Gao *et al.* (2002) involved two pieces of cotyledon from the same seed that were treated individually to produce transformed and nontransformed plants, thereby overcoming the disadvantage of transformants originating from different cotyledons that would differ both genetically and physiologically, because individual cotyledons are genetically heterogeneous. However, this technique does not maintain the genetic background of the

transformed cultivars or rootstock and has limited potential for pear breeding.

The techniques of transformation used for these different pear genotypes are quite similar (Table 2). Due to the fact that all genotypes do not respond similarly to the same procedure of transformation, some variations have been reported.

- *Nature of the explants.* In 75% of the procedures published, young expanded pear leaves were used as explants. The regeneration of transformed lines from leaves has proved to be enhanced by placing the leaf segment abaxial side up on the medium, possibly due to increased oxygen exchange since stomata are located abaxially. The other explants used are the cotyledon, internode, and axillary shoot meristem.
- *Inoculation procedures.* Two inoculation procedures have been used. The first consists of wounding the leaves with a scalpel dipped in the inoculum (Mourgues *et al.*, 1996). The second is to bathe leaves in the inoculum for a few minutes (Gao *et al.*, 2002).
- *Strains of *Agrobacterium tumefaciens* used.* 65% of the pear transformation procedures were based on use of *A. tumefaciens* EHA compared to *A. tumefaciens* strain A281 (5%) (Merkulov *et al.*, 1998), C58C1 (15%), CBE21 (5%) (Lebedev *et al.*, 2002a, b), or AK10 (5%) (Kaneyoshi *et al.*, 2001) for the T-DNA integration.
- *The selectable marker used.* In 95% of cases, kanamycin has been used as selectable marker. Concentration of kanamycin used for the regeneration of transgenic apple varied according to the cultivar. Another antibiotic tested as a selectable marker was hygromycin (Lebedev *et al.*, 2002a, b).
- *Other modifications.* Other modifications have been made to these procedures to increase the transformation efficiency. These modifications included the use of a plant phenolic compound (acetosyringone) to induce the expression of several virulence genes in *A. tumefaciens*, the gelling agent, the growth regulators (Table 1), the source of carbon (sucrose or sorbitol), the binary vector, and the antibiotics used (cefotaxime, timentin).

Although some modifications to the initial pear transformation procedure of Mourgues *et al.*

(1996) have been developed for each pear cultivar, the general structure of the procedure is the same (Figure 1).

2.2 Genetic Engineering in Pear

2.2.1 Disease resistance

2.2.1.1 Fire blight

The most important disease of pear is fire blight, a disease of American origin. It was first reported in the Hudson Valley of New York in 1784. It has been known as the most destructive bacterial disease of the *Maloideae* (pear, apple, and quince) and other members of the Rosaceae family for over 200 years and in fact is the first plant disease proved to be of bacterial origin (Norelli *et al.*, 2003). This disease is caused by the necrogenic endobacterium *E. amylovora*, which is capable of infecting blossoms, fruits, vegetative shoots, woody tissues, and rootstock crowns. Upon entering plants through natural openings or wounds, the bacterium causes necrosis that develops quickly along the shoots to the main branches, producing the characteristic symptom of this disease: a necrotic shoot blight

that can kill a tree in one season (Thomson, 2000). In nonhost plants, such as *Arabidopsis thaliana* or tobacco, *E. amylovora* elicits a hypersensitive response (HR) characterized by a rapid and localized collapse of tissues.

E. amylovora, is a gram negative bacterium and its anatomy, physiology, and serology have been well described (Paulin, 2000). Twenty years ago, factors involved in its pathogenicity and virulence have been identified. Transposon mutagenesis led to the identification of three key groups of genes responsible for pathogenicity: (1) The cluster of *dsp* genes (disease specific gene, Boucher *et al.*, 1987) is strictly required for pathogenicity (Gaudriault *et al.*, 1997; Bogdanov *et al.*, 1998b). Two *dsp* genes were isolated, *DspA* or *E*, which encodes a pathogenicity factor homologous to the *Avr E* gene of *Pseudomonas syringae*. The *Dsp B* or *F* gene encodes a protein similar to a chaperone protein of pathogenic bacteria such as *Yersinia* and *Shigella* (Gaudriault *et al.*, 1997; Bogdanov *et al.*, 1998a, b); (2) The *ams* gene (amylovoran synthesis gene) is required for synthesis of extracellular polysaccharides (EPS) (Belleman and Geider, 1992); (3) The *hrp* (hypersensitive reaction and pathogenicity gene) cluster is necessary for pathogenicity on host plants and HR elicitation on nonhost plants

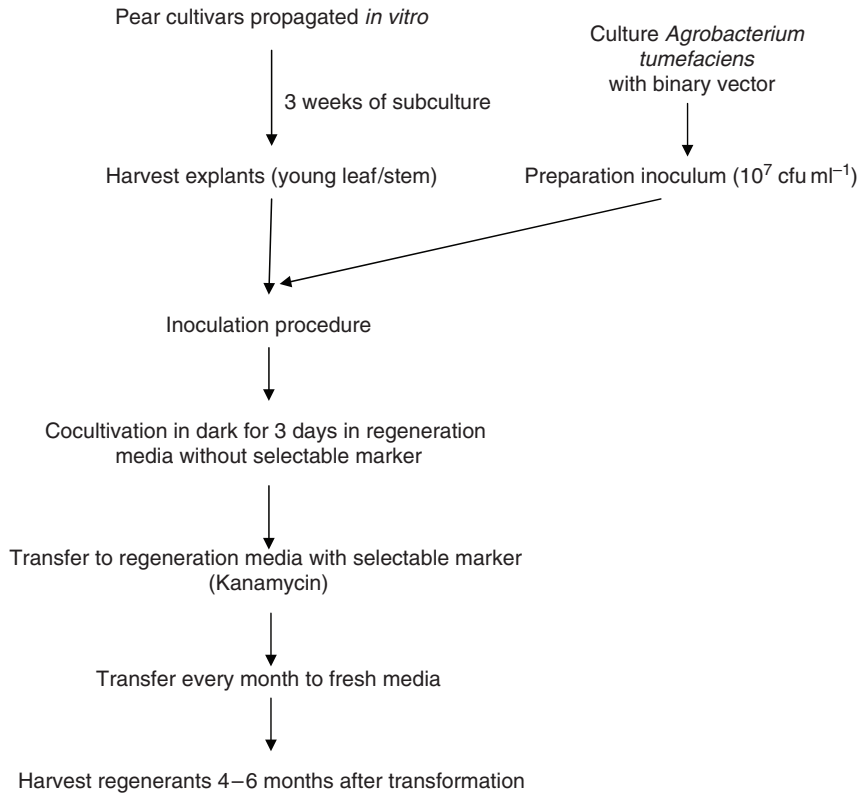

Figure 1 Representation of the pear transformation procedure

(Barney *et al.*, 1990; Kim and Beer, 2000). The *hrp* gene cluster has been characterized in several other pathogenic bacteria such as *Xanthomonas* and *Ralstonia* (Lindgren, 1997). This cluster encodes components of a Type III secretion pathway (Hueck, 1998), and regulatory and secreted proteins. Today, at least seven proteins of *E. amylovora* are known to be secreted via the Hrp pathway: DspA/E, OrfB, HrpW, HrpA, HrcQ, HrpJ, and HrpN_{Ea} (Kim and Beer, 2000). Harpin N_{Ea} was the first secreted protein characterized by molecular analysis (Wei *et al.*, 1992). This protein is a 44-kDa glycine-rich protein, which lacks cysteine, is heat stable, and is able to induce an HR when purified and infiltrated into tobacco leaves. Besides three key pathogenicity factors, *E. amylovora* produces a siderophore belonging to the desferrioxamine family, which acts as virulence factor (Dellagi *et al.*, 1998).

The economic impact of fire blight is difficult to determine, as losses are rarely recorded when

they are low (a few flower clusters on a few trees killed within a season) and a single outbreak can disrupt orchard production for several years. However, in recent years, fire blight has caused serious losses around the world (Norelli *et al.*, 2003). While outbreaks are sporadic in occurrence, they often result in significant losses when they do occur, in terms of trees damaged and killed, loss of millions of dollars (Aldwinckle *et al.*, 2003). In 2000, southwest Michigan experienced a severe fire blight epidemic and reported a \$42 million economic loss for the region that resulted in the removal of 300 000 apple trees covering approximately 2000 acres. Losses and costs in many other states and countries, such as New Zealand, Italy, and Washington State in 1998 were also very substantial.

The strategies of ribosomal DNA (rDNA) technology to improve the resistance to fire blight are aimed at producing incompatible interactions between the plant and the pathogen, by means

of restricting the multiplication of the pathogen in the plant after infection. These outcomes can be obtained in different ways: (1) production of antimicrobial proteins; (2) inhibition of bacterial pathogenicity factors; and (3) enhancement of natural plant defense.

Production of antimicrobial protein Antibacterial proteins are important components of the overall antimicrobial defense mechanisms of many groups of animals, including arthropods, amphibians, and mammals (Mourgues *et al.*, 1998). Probably acting in synergy, they have a bactericidal action on a large range of gram-negative and gram-positive bacteria. Genes encoding antimicrobial proteins that have been cloned and expressed in apple and pear in an attempt to confer resistance to fire blight disease include attacin E, cecropin, and lysozyme (Table 3).

Attacins and cecropin are antimicrobial peptides found in the hemolymph of *Hyalophora cecropia* in response to bacterial infection (Hultmark *et al.*, 1980). These two peptides have no known enzymatic activity. They are active against the membrane of gram-negative bacteria. Attacin causes an increase in the permeability of the outer membrane (Carlsson *et al.*, 1991) and cecropin induces pore formation in the bacterial membrane (Flink *et al.*, 1989), both effects resulting in death of the bacterial cells. Attacin E and synthetic analogs of cecropin (SB-37 and Shiva 1) under the control of inducible (Pin2) and constitutive (CaMV 35S) promoters have been introduced into the Passe Crassane genotype to enhance resistance to *E. amylovora* (Table 3). Some of the transgenic Passe Crassane lines expressing these genes show partial resistance to fire blight *in vitro* (Reynoird *et al.*, 1999a, b; Malnoy *et al.*, 2000). The level of resistance was significantly greater in greenhouse and *in vitro* when the lysozyme gene was integrated into the Passe Crassane genome (Malnoy *et al.*, 2000). Lysozymes are bacteriolytic enzymes, which have been characterized from phages, bacteria, fungi, plants, and animals (Jollès and Jollès, 1984). They are responsible for weakening the cell wall, leading to eventual lysis of the bacteria (Düring, 1996). Some lysozymes also have chitinase activity (EC 3.2.1.14) resulting from random hydrolysis in the chitin. Their mode of action is such that they only act as bactericides to gram-positive bacteria

(Boman and Hultmark, 1987). However, they have displayed activity against gram-negative bacteria when they act in synergy with other antimicrobial peptides (cecropin or attacin) (Boman and Hultmark, 1987). A construct that associated the *T4 lysozyme* gene with *attE* under control of the Pin promoter was made by Ko *et al.* (2002), and integrated into the genome of Passe Crassane (Malnoy *et al.*, 2000). However, transgenic lines containing both attacin and T4 lysozyme genes were not significantly more resistant than the Passe Crassane transgenics for attacin or T4 lysozyme alone, indicating that there was no *in planta* synergy between these two genes with respect to resistance to *E. amylovora* (Malnoy *et al.*, 2000).

Inhibition of bacterial pathogenicity or virulence factors Expression by the plant of any mechanism inhibiting bacterial pathogenicity or virulence factors should lead to resistance or reduced susceptibility. However, even though several of these factors are well known for many bacterial plant pathogen species, in particular for *E. amylovora*, this knowledge has only started to be exploited to develop strategies for engineering fire blight resistance. Two strategies to inhibit pathogenicity or virulence factor of *E. amylovora*, have been reported in pear: degradation of the capsular extracellular polysaccharide (EPS) amylovoran, and competition for assimilation of iron through the siderophore.

Degradation of the capsular exopolysaccharide (EPS) The capsular EPS plays an essential role in pathogenicity: bacterial mutants that do not produce EPS fail to colonize host plants (Belleman and Geider, 1992; Bernhard *et al.*, 1993). Indeed, the capsule functions not only to bind water, ions, and nutrients, but also as a protective layer to reduce possible recognition and response by the host (Romeiro *et al.*, 1981). A protective role of EPS against oxidative stress had also been proposed by Kiraly *et al.* (1997). However, recent studies on the interaction between pear and *E. amylovora* have shown no role of the capsule in the elicitation of the oxidative burst or in the protection of the bacteria against active oxygen species (Venisse *et al.*, 2003).

The composition and sugar linkages of EPS are characteristic of a bacterial species (Geider,

2000). The major EPS of *E. amylovora*, called amylovoran, is composed of repeated units of three galactose residues, a side chain of glucuronic acid, and another galactose residue, which carries acetyl groups and a pyruvate residue (Nimtz *et al.*, 1996). Amylovoran biosynthesis requires a large number of enzymes encoded by the *ams* (amylovoran synthesis) cluster of genes located adjacently in the 17 kb region of the bacterial chromosome (Bugert and Geider, 1995). This EPS can be naturally degraded by a protein depolymerase of some bacteriophages. Hartung *et al.* (1988) have isolated an EPS-depolymerase gene from phage ϕ Ea1h. The encoded enzyme, when applied topically, reduced fire blight symptoms in pear slices (Kim and Geider, 2000). The purified protein has an optimal activity at low pH, which is similar to the acidic conditions encountered in damaged plant cells during infection.

The depolymerase gene from phage ϕ Ea1h was constitutively expressed in pear (Malnoy *et al.*, 2002, 2005a). In Passe Crassane expression of the depolymerase gene in 15 independent transgenic clones led, in general, to very low depolymerase activity, although relatively high expression at transcriptional and translational levels was observed. Only two of these transgenic clones consistently showed a decrease in fire blight susceptibility *in vitro* and in the greenhouse. These clones were also among the highest expressers of depolymerase at the RNA and the enzyme activity levels. These results in pear are comparable to the preliminary results reported on transgenic apple expressing the same depolymerase gene (Hanke *et al.*, 2003). The partial fire blight resistance observed in these transgenic pear and apple lines could be explained by the mode of action of the depolymerase. Indeed, in capsule degradation assays using purified depolymerase, obtention of totally uncapsulated *E. amylovora* cells required high enzyme concentrations (Kim and Geider, 2000). Thus, the authors assumed that the amount of depolymerase produced in most of these transgenic clones is below the necessary threshold for sufficient destruction of EPS capsules at a high concentration of inoculum, but partly effective when the concentration of inoculum is lower. To achieve better control of fire blight in very susceptible pear cultivars, improvements in this strategy might be obtained by directing the depolymerase protein fused with a signal peptide

to the intercellular spaces and by upregulating this gene with a translational enhancer (e.g., AMV, alfalfa mosaic virus).

Decreasing iron availability in plants *E. amylovora* produces a siderophore belonging to the desferrioxamine family, which is a virulence factor in bacteria (Dellagi *et al.*, 1998). This siderophore allows the pathogen to overcome conditions of low iron availability encountered in host tissues and has a protective effect against toxicity of active oxygen species (Expert *et al.*, 2000; Venisse *et al.*, 2003). Thus, decreasing iron availability in transgenic plants might be an attractive approach to limit bacterial invasion in the host tissue (Expert *et al.*, 1996).

Lactoferrin, found in mammalian milk, is a member of a family of iron-binding glycoproteins. Lactoferrin genes from various sources (human and bovine) show significant homology and encode a single polypeptide chain of about 700 amino acids (molecular mass of approximately 80 kDa) with an iron binding site in each of the similar amino and carboxy terminal regions (Pierce *et al.*, 1991). Their mode of action against bacteria is not only bacteriostatic but also bactericidal (Kalman and Arnold, 1988; Borthier *et al.*, 1989). A potential bactericidal domain exists in a short peptide sequence, termed lactoferricin, near the N-terminal region of the lactoferrin molecule, which can be released by proteolytic cleavage (Bellamy *et al.*, 1992a, b). Expression of a human lactoferrin gene transferred into the tobacco genome has shown that the extract from transgenic calli has a potent activity against a large spectrum of microorganisms including gram-positive and gram-negative bacteria (Mitra and Zhang, 1994). Moreover, expression of this gene conferred increased resistance to *Ralstonia solanacearum* (Zhang *et al.*, 1998). Malnoy *et al.* (2003b) have examined the ability of bovine lactoferrin, which is slightly more effective than human lactoferrin when controlled by the *CaMV* 35S promoter, to reduce fire blight susceptibility in pear. Most of their transgenic clones demonstrated significant reduction in susceptibility to *E. amylovora in vitro* (17%) and in the greenhouse (60%). These transgenic clones also exhibited a significant reduction of symptoms when inoculated with two other bacterial pathogens of pear, *P. syringae* pv. *syringae* and *A. tumefaciens*. Moreover, this

increase in bacterial resistance was correlated with an increase in root ferric reductase activity and leaf iron content. Despite negative effects on the growth of a few clones, their results indicate the potential of lactoferrin gene transformation to protect pear from fire blight through increased iron chelation. To increase the level of fire blight resistance, they proposed to use the more efficient iron-chelator, plant ferritin, which is able to chelate 4000 iron atoms (Goto *et al.*, 1998), whereas lactoferrin chelates only two iron atoms. Different ferritin genes have been overexpressed in transgenic plants for increased nutritional quality (Goto *et al.*, 1999), for bioremediation of heavy-metal-polluted environments (Vansuyt *et al.*, 2000), and for tolerance to oxidative damage and pathogens (Deak *et al.*, 1999). However, the constitutive expression of transgenic ferritin also has profound pleiotropic effects, which can be either positive (e.g., enhanced growth of transgenic lettuce reported by Goto *et al.* (2000)) or negative (e.g., reduced growth and chlorophyll content of transgenic tobacco reported by Van Wuytswinkel *et al.* (1998)). In order to avoid the potential negative effects of ferritin overexpression in pear, E. Chevreau placed this gene under the control of the pathogen inducible promoter *sgd24*, which is locally and specifically activated by pathogens in pear (personal communication). This promoter also displays an average level of expression that is much lower than the constitutive expression driven by the CaMV 35S promoter (Malnoy *et al.*, 2003a).

Enhancement of natural plant defenses Plant defense mechanisms are activated during incompatible and compatible reactions. However, in the case of a compatible interaction, the speed and level of expression of defense genes are insufficient to prevent disease development in the plant. Some strategies depend on blocking the progress of the pathogen in order to allow adequate activation of defense pathways of the plant.

During plant–pathogen interactions, pathogens secrete compounds called elicitors that induce plant defense mechanisms at variable speeds. These compounds when isolated from bacteria or fungi might be used to protect plants against their pathogens. These inducing substances can be classified into two groups: those interacting with the plant following the gene-for-gene model of

Flor (1956) (*avr* genes) and those inducing the defense pathways of the plant. A bacterial *avr* gene conferred almost total resistance to plants expressing the corresponding resistance gene; in the case of *Arabidopsis* expressing the transgene *avrB* (Gopalan *et al.*, 1996) or *avrRpt2* (Mc Nellis *et al.*, 1998), resistance was expressed as an HR. But it is more probable that this type of resistance will be bypassed by pathogens compared with strategies using an elicitor with direct (PopA, Harpin N) or indirect action (pectate lyase).

Harpin N_{Ea} is also a known inducer of systemic acquired resistance (SAR) in plants. In *A. thaliana*, Dong *et al.* (1999) demonstrated that harpin elicits resistance to *Peronospora parasitica* and *P. syringae* pv. *tomato*, accompanied by induction of the SAR genes *PR-1* and *PR-2*. Harpin N_{Ea} acts through the *NIM1*-mediated SAR signal transduction pathway in a salicylic acid-dependent fashion. The site of action of harpin in the SAR regulatory pathway is upstream of salicylic acid. Similar induction of SAR was demonstrated in cucumber following treatment with harpin P_{SS} (Strobel *et al.*, 1996). The practical potential of harpin N_{Ea} as an elicitor of defense reaction has been tested on several plant species challenged with various disease agents (Wei and Beer, 1996). This work led to the registration of a new biological pesticide, Messenger, whose active ingredient is harpin N_{Ea}. The elicitors appear to trigger a common network of signaling pathways that coordinate the defense responses of plants.

In order to create novel mechanisms for fire blight resistance in pear, some pear (Malnoy *et al.*, 2005b) lines transformed with a construct containing the elicitor harpin N_{Ea} from *E. amylovora* with constitutive promoter CaMV 35S was employed. Stable integration of Harpin N_{Ea} with the constitutive CaMV 35S promoter did not cause any detectable damage in the transgenic Passe Crassane clones. Integration of harpin N_{Ea} in the genome of Passe Crassane significantly increased the *in vitro* fire blight resistance of 10 clones out of 17. Compared to the nontransformed control, the reduction of symptoms was 36% and 58% with an inoculum concentration of 10⁷ and 10⁶ cfu ml⁻¹, respectively. These results are encouraging, because Passe Crassane is one of the pear genotypes most susceptible to fire blight. These transgenic lines can also help promote a better understanding of the role of harpin N_{Ea} in the induction of fire blight resistance in the

transgenic clones. It will also be interesting to look at the behavior of these transgenic lines in response to some other pathogens of pear.

2.2.1.2 *Pear psylla*

Pear psylla, *C. pyricola* Foerster, is a major pest of pear in the United States that feeds primarily on phloem tissue of pear. This pest is host specific to certain *Pyrus* spp. (Bell and Stuart, 1990). Changes in pear plant chemistry, physiology, or morphology brought on by the expression of foreign genes could impact the biology and behavior of pear psylla. The biology and behavior of pear psylla, *C. pyricola* Foerster, on a transgenic clone of Bartlett pear, containing a synthetic antimicrobial gene, *D5C1*, was compared with that of a nontransgenic parental clone to determine whether there were any nontarget effects. Short-term studies (<7 days) indicated pear psylla adults preferred to settle and oviposit, and nymphs fed more and developed slightly faster, on transgenic pear compared with nontransgenic pear. In contrast, a long-term study (32 days) on psylla colony development showed considerably fewer eggs, nymphs, and adults were produced on transgenic pear. Although adults reared on transgenic pear did not show weight reduction, females produced fewer eggs and nymphal hatch was significantly reduced on the transgenic pear clone. The fourfold reduction in psylla population levels that resulted on this disease resistant transgenic pear line would be an added benefit to a pear integrated pest management (IPM) program (Puterka *et al.*, 2002).

2.2.2 Dwarfism and rooting ability in rootstocks

Dwarfing characteristics of fruit tree rootstocks are of great importance for commercial production. Dwarf rootstocks are useful for high yield fruit production because trees can be planted close together; labor is reduced because the pears can be harvested without using ladders. Rootstocks have been developed for this purpose, but these dwarf rootstocks are more difficult to propagate from cuttings compared to vigorous ones. Several genes causing reduced growth have been identified

in apple (Jasik *et al.*, 1997). The *rol* (*A*, *B*, *C*, and *D*) genes from *Agrobacterium rhizogenes* and the plant phytohormone genes have been shown to exert dwarfing properties (Jasik *et al.*, 1997). The three genes (*rolA*, *rolB*, and *rolC*) derived from the Ri plasmid of *A. rhizogenes* were used to improve the dwarfing ability of several apple rootstocks.

The *rolB* gene has been found to be the most effective among the *rol* (root loci) genes in promoting root formation; this gene has been applied in genetic transformation to improve adventitious rooting of some recalcitrant plants (Rugini *et al.*, 1991; Nilsson *et al.*, 1997). This gene has been successfully expressed in the rootstock BP10030 (Zhu *et al.*, 2003). The transgenic rootstock expressing the *rolB* gene has an increased rooting ability and a shortened stem length. The significant improvement in the rooting ability of the transformed lines BP10030 makes mass production of this rootstock possible at a low cost. Since BP10030 is a dwarfing pear rootstock of *Pyrus* type, the use of the *rolB* transgenic plants of this rootstock will brighten the perspective for commercial pear production in the near future. One concern in using transgenic plants is the stability of the altered trait in offspring. However, this may not apply to pear rootstocks because fruit tree rootstocks are propagated vegetatively. The risk of losing the transgene *rolB* is thus very low, compared to annual crops where the segregation occurs after crossing and selection (Zhu *et al.*, 2003). Nevertheless, before any commercialization of these transgenic lines, Zhu *et al.* (2007) are investigating the influence of these lines on growth and development of pear cultivars grafted onto them to evaluate the stability of transgene expression in greenhouse and in the field. Their preliminary results show that, for the same cultivar, no differences in bud break, flowering, and flower numbers were found between the transgenic and nontransgenic rootstocks. The plant height and stem diameter were reduced for the vigorous cultivars grafted on the *rolB* rootstocks compared with the untransformed rootstocks (Zhu *et al.*, 2007), and no transgene was found in the untransformed scion cultivars (Zhu *et al.*, 2007). Integration of the *rolC* gene also gave similar results in Beurre Bosc (Bell *et al.*, 1999). Their preliminary observations in the greenhouse showed that the transgenic line expressing the *rolC* gene had reduced height, number of nodes, and leaf area.

2.2.3 Flowering time

In the development of all woody plants from seed, there is a juvenile phase, lasting at least 4 years in pear (Visser, 1976), during which flowering does not occur and cannot be induced under normal conditions (Hackett, 1985). In the tree fruit industry, it is important to accelerate flowering by reducing the juvenile or vegetative phase of the trees after planting in order to facilitate the earliest possible production of fruit. In fruit breeding, various practical techniques have been considered to accelerate the flowering of seedling. The most striking advances of the genetic control of flowering time come from studies in *Arabidopsis* (Levy and Dean, 1998, Pineiro and Coupland, 1998). Several genes that control flowering time have been isolated, namely, *LEAFY* (*LFY*) (Weigel *et al.*, 1992), *APETALA1* (*API*) (Mandel *et al.*, 1992), *TERMINAL FLOWER 1* (*TFL1*) (Ohshima *et al.*, 1997), and *FLOWERING LOCUS* (*FT*) (Kardailski *et al.*, 1999). Overexpression of the citrus homolog *CiFt* gene in two pear cultivars La France and Ballade induced *in vitro* flowering in 13 lines (Matsuda *et al.*, 2006). Early flowering phenotype was closely correlated with *CiFT* expression level. Similar work is currently under way in Israel, where silencing of *TFL1* by RNA interference (RNAi) induced early flowering in the pear cultivar Spadona (M. Flaishman, personal communication).

2.2.4 Control of transgene expression

The genetic construct integrated into the pear genome to control the expression of the gene of interest must contain a DNA sequence encoding the active protein and several regulatory sequences. These sequences control when, how, and where the protein of interest will be expressed in the plant. Among these regulatory sequences, the promoter identifies the coding region and allows messenger RNA (mRNA) transcription, and also determines when, and in some cases, under what conditions transcription is initiated. The CaMV 35S promoter from cauliflower mosaic virus has been used widely in transgenic plants; in pear it controls 80% of transgenes integrated in the pear genome because it provides continuous expression regardless of developmental stage

in most plant tissues (constitutive expression) (Table 2). Duplication of the upstream (5') DNA sequences of the 35S promoter results in elevated levels of transcription (Kay *et al.*, 1987). With such promoters, a gene is expressed in the majority of tissues during most phases of plant growth and development. This limited temporal and spatial regulation may be suitable for proof of concept experiments, but presents a number of potential drawbacks for use in genetically improved crops. For example, the presence of transgenes driven by constitutive promoters may result in homology dependent gene silencing, particularly when the promoter is also highly active (Vaucheret *et al.*, 1998). Thus, gene expression under the control of inducible promoters (tissue-, development stage-, pathogen-specific) is preferred in any strategy to produce transgenic plants with transgene-mediated improvements in resistance to pathogens. This targeted gene expression could be advantageous in providing resistance where and when needed, limiting the amount of transgenic protein in fruit, reducing the plant's energy cost for transgenic protein synthesis, and reducing unnecessary exposure of nontarget organisms to the protein (Norelli and Aldwinckle, 2000).

Knowledge of genes involved in plant pathogen interactions is still limited in pear. Therefore, different inducible promoters isolated from tobacco and potatoes have been used in experimental studies in response to *E. amylovora* infection and different abiotic stresses, and may be useful in commercial cultivars.

Two gene families have been identified in tobacco, whose expression in response to bacterial pathogens is rapid and intense: the "*hsr*" (hypersensitivity related) and "*str*" (sensitivity related) gene families (Marco *et al.*, 1990). The *hsr203J* (Pontier *et al.*, 1994), *aig1* (Reuber and Ausubel, 1996), and *hin1* genes (Gopalan *et al.*, 1996) belong to the *hsr* family. These genes are specifically (or preferentially) activated by signal molecules generated during the hypersensitive reaction (HR). Among these genes, only the *hsr203J* promoter has been fully characterized (Pontier *et al.*, 1994, 1998, 2001). *Hsr203J* expression occurs rapidly and locally when tobacco leaves are inoculated with the phytopathogenic bacterium *R. solanacearum* (Pontier *et al.*, 1994). The *hsr203J* promoter is neither developmentally nor tissue-specifically regulated and does not respond to

potential inducers such as environmental stimuli or endogenous plant signal molecules (Pontier *et al.*, 1998). In pear (Malnoy *et al.*, 2003a) and apple (Reynold *et al.*, 2000), the *hsr203J* promoter is activated after *E. amylovora* infection, but at a level insufficient (2% of the level of expression obtained with the CaMV promoter in pear) to be used to provide effective expression of antibacterial transgenes. Genes from the “*str*” family are activated during the early stages of compatible interaction (disease) as well as in incompatible (HR, resistance) interaction. The *str246C* gene isolated from tobacco belongs to the *str* family (Froissard *et al.*, 1994). The promoter of this gene is not only regulated by pathogens and elicitors, but also by other environmental and developmental stimuli, such as hormones, wounding, and heavy metal treatments (Gough *et al.*, 1995). Furthermore, it harbors a regulatory region (184 bp fragment of *str246C* promoter: *sgd24* promoter), which is sufficient for the induction of promoter activity in response to bacteria (Gough *et al.*, 1995). The *str246C* promoter was rapidly activated in pear during compatible and incompatible interactions, by wounding and following the application of several elicitors (capsicin, cryptogein, and harpin) and phytohormones (salicylic acid and methyl jasmonate) (Malnoy *et al.*, 2003a). The *sgd24* promoter, a deletion derivative of *str246C*, exhibited a low level of expression after bacterial inoculation, was weakly activated by wounding and elicitors, and was not activated by phytohormones (salicylic acid and methyl jasmonate) (Malnoy *et al.*, 2003a). Interestingly, the *sgd24* promoter was locally activated in pear, whereas the *str246C* promoter was activated systemically from the infection site. Both promoters, *str246C* and *sgd24*, are less active than the *CaMV* 35S promoter in pear, but their pathogen responsiveness makes them alternatives to use to drive the expression of transgenes to promote bacterial disease resistance.

2.2.5 Selectable marker

Selectable marker genes are widely used for the efficient transformation of crop plants. In most cases, selection is based on antibiotic or herbicide resistance. These marker genes are preferred because they tend to be most efficient (e.g., in

pear up to 80% transformation rate with the *nptII* gene for kanamycin resistance). Due to concerns about acceptability of antibiotic resistance genes in fruit cultivars, considerable effort is being put into developing a suite of strategies (site-specific recombination, homologous recombination, transposition, and co-transformation) to eliminate the marker gene from the nuclear or chloroplast genome after selection (Miki and McHugh, 2004). Some current efforts are emphasizing systems in which the marker genes are eliminated efficiently soon after transformation (Schaart *et al.*, 2004). Alternatively, transgenic pear can be produced by the use of marker genes that do not rely on antibiotic or herbicide resistance but instead promote regeneration after transformation. Chevreau *et al.* (2007) have shown a promising effect of the *Vr-ERE* gene for the selection of transgenic lines. The benzaldehyde (BA), substrate of *Vr-ERE*, is able to inhibit adventitious bud regeneration. BA can be used instead of kanamycin but the efficiency of the selection pressure is not yet proven.

2.3 Testing of Activity and Stability of Expression of Transgenes, Yield, and Quality

With respect to the release of transgenic woody plants the stability of the integrated transgenes and their long-term expression is one of the main objectives in monitoring and risk assessment of genetically engineered plants. Stable integration and expression of the transgenes is important for fruit trees, which have an exceptionally long production time compared with annual crops. Different groups have been studying the stability of the expression of the transgenes in transgenic apple. James *et al.* (1995) showed stable expression and Mendelian inheritance of the transgenes in transgenic Greensleeves. They showed a 1:1 segregation of the *nos* gene in the R₁ transgenic apple progeny. In pear, the study of the stability of the expression of the transgene in transgenic pear is being undertaken by several groups. A first report published by Hao *et al.* (2005) established by polymerase chain reaction (PCR) and Southern analysis the stable maintenance of the *gus* gene in transgenic pear (*P. pyrifolia* var. Okusankichi) recovered from slow-growth

culture or cryopreservation. No data have yet been reported on transgene stability in transgenic pears in the field.

2.4 Regulatory Measures Adopted

Regulatory measures adopted and risks concerning pear GE crops are the same as those described in the chapter of apple transformation (see Apple).

3. FUTURE ROAD MAP

Concerning the nature of the actual genes functioning in GE crops, the regulatory agencies, growers, consumers, and perhaps nongovernmental organizations (NGOs) are thought more likely to accept the GE product if promoters and genes from the host family are used without selectable markers. The production of GE pear cultivars transformed with genes from different organisms was the first generation of GE cultivars to prove that the concept of increasing resistance by genetic engineering is effective. The next generation of GE pear lines will not contain antibiotic resistance selectable marker genes and will rely on altered expression of native pear genes for their improved disease resistance, architecture, and quality.

One of the recurring themes of the debates concerning the application of genetic transformation technology has been the role of intellectual property rights (IPR). This term covers both the content of patents and the confidential expertise usually related to methodology and referred to as “trade secrets” (Dunwell, 2005). Although few of the patents in this area have any real commercial value, there are small number of key patents that restrict the “freedom to operate” of new companies seeking to exploit the methods. Over the last 20 years, these restrictions have forced extensive cross licensing between ag-biotech companies and have been one of the driving forces behind the consolidation of these companies. Although such issues are often considered of a little interest to the academic scientist working in the public sector, they are critical for practical use of the technologies they develop. During the period since the production of the first transgenic

plants, a wide diversity of patents have been sought on all aspects of the process, ranging from the underlying tissue culture methods through the means of introducing the heterologous DNA, to the composition of the DNA construct so introduced (Kesan, 2000).

A recent advance that may circumvent the IPR limitation to *Agrobacterium* transformation technology is the development of gene transfer techniques using other bacteria, such as *Sinorhizobium* (Broothaerts *et al.*, 2005). It is claimed that these methods may offer an open source alternative to the established transformation technologies.

1. INTRODUCTION

1.1 History, Origin, and Distribution

Peaches were probably the first fruit crop domesticated in China about 4000 years ago (Hesse, 1975). Peaches were moved to Persia (Iran) along silk trading routes. In fact, the epithet *persica* denotes Persia, which is where Europeans thought peaches originated.

Alexander the Great brought the peach to Greece. Greeks and especially Romans spread the peach throughout Europe and England starting in 300–400 BC (Hedrick, 1917). Peaches were brought to America with explorers of the 16th–17th centuries, with the Portuguese introducing it to South America and the Spanish to the northern Florida coast of North America. Due to the fact that stone fruits have the seed encased in a hard, lignified structure (stone) obviates special storage conditions thus facilitating their dispersion over long distances.

1.2 Botanical Description

Peach and nectarine, *Prunus persica* (L.) Batsch belong to *Prunus* genus, subfamily Prunoideae. This is the most economically valuable genus in the Rosaceae family after *Malus*. Fruits of the genus *Prunus* are described as “stone fruits” due to the

encasement of the seed within a lignified stonelike endocarp. Common *Prunus* fruits include, other than peach and nectarine, European plum (*P. domestica* L.), Japanese plum (*P. salicina* Lindl.), sour cherry (*P. cerasus* L.), sweet cherry (*P. avium* L.), apricot (*P. armeniaca* L.), and almond (*P. dulcis* Miller). The flesh (mesocarp) of the almond fruit is hard and leathery and the seed is the edible portion.

All commercial varieties of peach and nectarines are *P. persica*, a diploid ($2n = 16$) (Jelenkovic and Harrington, 1972).

Tree growth habits include columnar, dwarf, spreading, and weeping (Faust and Timon, 1995). Peach flowers are borne singly on short peduncles (almost sessile) from lateral buds on 1-year-old wood; usually 1–2 flower buds/node, with few spurs forming, although spur-type trees have been reported (Scorza, 1987). Flowers exhibit cleistogamy, pollinating themselves prior to opening.

The fruit is a drupe with a thin epidermis, fleshy mesocarp, and a stony endocarp, that together with the seed forms a propagation unit comparable to botanical seed surrounded by its protective testa. Fruits can be beaked, round, flat shaped, yellow, white, red, melting or nonmelting fleshed; clingstone or freestone (describing adherence of the flesh to the stone); and with smooth or pubescent epidermis. This last characteristic is the only difference between

peaches and nectarines, a character that segregates as a simple trait presumably controlled by a single gene or a few closely linked genes. Trees are precocious, producing some fruit in the second year after planting. Peaches require extensive thinning (80–95% of flowers) for proper fruit size development. Fruit thinning is usually done by hand 30–45 days after full bloom, leaving about 1 fruit per 15 cm of 1-year-old shoot length. The first commercial crop is generally harvested in year 3, with maximal yields reached by year 5–7.

1.3 Economic Importance

In temperate regions, the family Rosaceae is very important in economic terms. Its commercially valuable members include fruit producing (e.g., stone fruits, apples, pears, brambles, and strawberries), nut producing (almond), lumber producing (e.g., black cherry), and ornamental (e.g., roses, flowering cherry, quince) species.

Peach is grown on all continents except Antarctica. Generally, commercial production lies between latitudes 30° and 45°. The major limiting factors for expansion of commercial production areas are extreme cold temperatures below –35 °C to –40 °C or insufficient length of cold temperature to satisfy dormancy requirements. Table 1 shows the worldwide production and harvest area for peaches and nectarines in the last 3 years.

Peaches have few marketing niches other than fresh and canned fruit. Melting flesh freestone peaches are sold fresh, and nonmelting flesh peaches are usually canned. The utilization in the United States is about 98% of nectarines marketed fresh, 45–50% of the commercial peach crop is marketed fresh, 40–43% canned, 4–8% frozen, 1–2% dry, and 2–3% others (as jam, baby food, etc.).

Like all members of the genus *Prunus*, peach leaves, flowers, and especially seeds and bark contain cyanogenic glycosides, such as amygdalin and prunasin. These compounds are toxic or lethal in large doses. However, in plant tissues, cyanide is low enough in concentration to be considered therapeutic, particularly for cancer treatment, and has been used for this purpose since at least 25 BC. In fact it has been shown that peach flower extracts can prevent ultraviolet-induced carcinogenesis in humans (Heo *et al.*, 2001).

1.4 Traditional Breeding

Hybridization has been used to develop most peach and nectarine cultivars and it remains as the dominant technology. Uncontrolled hybridization involves little more than collecting seed from trees that may be self- or cross-pollinated or a mixture of both. Controlled hybridization is the technique of applying pollen of the selected male parent

to the receptive stigma of the selected female parent. In the case of self-compatible species, such as peach, covering trees with an insect-proof material ensures self-pollination. While simple in concept, controlled pollination requires in-depth knowledge of crop biology and relies on exacting techniques for maximizing the number of hybrid progeny. Many of these techniques are described in Moore and Janick (1975).

Once a desirable phenotype is selected by the breeder, it can be reproduced indefinitely by vegetative propagation through the rooting of cuttings or more often through graftage of a scion cultivar onto a rootstock. This process makes possible the development of rootstocks selected for root characteristics (adaptation to specific soils, resistance to soil-borne diseases, insects, nematodes, etc.) and scion cultivars selected for fruit and production characteristics.

1.4.1 Rootstocks

The most important goals of peach rootstock breeding are resistance to diseases (*Armillaria* spp., *Phytophthora* spp., and *Verticillium dahliae*), insects (*Myzus* spp.), and nematodes (*Meloidogyne* spp., *Criconebella xenoplax*, *Pratylenchus* spp., *Mesocriconema xenoplax* and *Xiphinema americanum*), adaptation to heat and/or cold, vigor reduction of the scion, and good scion–rootstock compatibility (Reighard, 2002).

There are relatively few rootstock options for peach compared to other temperate tree fruits and, most rootstocks used are grown from seed. They are fairly uniform due to the self-pollinating, homogeneous nature of the peach. Several nematode tolerant rootstocks, rootstocks adapted to calcareous soil, and cold-hardy rootstocks have been released worldwide (Layne, 1987; Reighard, 2002).

Root-knot nematode (*Meloidogyne* spp.) resistant rootstocks are recommended for peach where this nematode is endemic. “Nemaguard”, “Nemared”, and “Guardian” are resistant to *Meloidogyne* (Nyczepir, 1991; Nyczepir *et al.*, 1999). *C. xenoplax*, the ring nematode and bacterial canker (*Pseudomonas syringae*) are involved in the peach tree short life (PTSL) syndrome (Beckman *et al.*, 2002; Okie and Scorza, 2002). PTSL causes significant losses in peach

in the southeastern region of the United States. Peach rootstocks have been screened for resistance to *C. xenoplax* (Okie *et al.*, 1987; Westcott and Zehr, 1991). “Guardian” is the only PTSL tolerant rootstock that is available (Okie *et al.*, 1994). The peach rootstocks “Bailey”, “Guardian”, “Rubira”, and “GF 305” are resistant to lesion nematodes (*Pratylenchus vulnus* and *Pratylenchus penetrans*) and dagger nematodes (*X. americanum*) (Reighard, 2002). Rootstock germplasm has also been screened for resistance to Cytospora canker caused by *Leucostoma* spp. (Scorza and Pusey, 1984; Chang *et al.*, 1989), and brown rot (*Monilinia fructicola*) (Gradziel and Wang, 1993) but no resistant rootstocks are available.

There are no compatible dwarfing stocks currently widely available, although *Prunus tomentosa* and *Prunus besseyi* have been used for dwarfing in research plantings, they are short lived. Several rootstocks with dwarfing potential have been released in Europe and the United States but none of them have been adequately tested to date (Scorza and Sherman, 1996; Perry *et al.*, 2000; Reighard, 2002; DeJong *et al.*, 2005).

1.4.2 Fruit cultivars

In general, the major breeding objectives for all commercial *Prunus* cultivars are high productivity and fruit quality, and resistance to pests and diseases (Scorza and Sherman, 1996). Cold hardiness, late blooming, and delayed softening are also important characteristics (Callahan *et al.*, 1991). In order to reach these goals, most major peach producing countries have active breeding programs and, at least, 60–70 new cultivars are released annually worldwide (Byrne, 2002).

Peaches are susceptible to many pests and diseases and only a few genotypes show some degree of resistance (Mehlenbacher *et al.*, 1990; Scorza and Okie, 1990). This lack of natural resistance to pests and diseases makes it difficult to obtain new resistant cultivars.

Peaches are widely adapted throughout their range, and except for extreme low or high chilling types, cultivars developed in one growing area are often utilized in many production regions. Therefore, in northern regions greater winter hardiness of both flower buds and whole trees is a major breeding consideration as it is the

most important factor limiting production in mid-continent and northern climates (Hesse, 1975; Mehlenbacher *et al.*, 1990; Scorza and Okie, 1990). Flower bud hardiness in peach has been shown to be a complex quantitative trait (Mowry, 1964).

The inheritance of peach fruit quality traits has been studied (Hesse, 1975; Scorza and Sherman, 1996). Breeding programs have produced very high quality fruits at maturity, however, for storage and shipping of fruit to nonlocal markets, these varieties must be picked earlier than full maturity resulting in fruits of lesser flavor and aroma in the market place. Therefore, increased firmness of ripe fruit is one of the major objectives in peach breeding. Fruit softening in peach has been studied and is related, at least in part, to endopolygalacturonase levels (Callahan *et al.*, 1989; Callahan *et al.*, 2004).

Architecture of trees is also another important breeding objective for some programs. Control of tree growth habit can reduce the need for pruning and may allow increased productivity in high-density systems (Scorza, 1984). Peach trees with columnar growth habit and high fruit quality have been produced and are under test in the United States and in Italy (Scorza *et al.*, 1989, 2000).

1.5 Limitations of Conventional Breeding: Use of New Tools, Biotechnology

Conventional breeding of temperate fruit trees is constrained by their long reproductive cycle, complex reproductive biology, and high degree of heterozygosity. In most cases, the characteristics that are desirable for commercial cultivars, including large fruit size, high coloration of the fruit epidermis, and firmness of the flesh, are recessive and/or multigenic (Bailey and French, 1949). Therefore, integration of adaptive traits from germplasm requires several rounds of introgressive backcrossing to fix the new trait and regenerate the high quality value traits in the original cultivated parent.

In addition to the time required for developing new cultivars, a significant amount of labor is required for pollen collection from male parents; individual hand emasculation of flowers of female parents; hand pollination; collection of seed from fruit developed from hybridization; seed stratification and germination; greenhouse

or nursery culture of seedlings; field planting of the seedlings; and selection and testing of superior phenotypes. Peach, a crop with a relatively short generation time of 3–4 years, has generally required from 10 years to 20 years from first fruiting to cultivar release. The relatively large areas necessary to grow segregating populations also add considerable expense to breeding programs.

The potential advantages of transformation for genetic improvement lie in the ability to target specific improvements in an otherwise known genotype, this process may require less time, labor, and field space. Perhaps most significantly transformation may provide for genetic improvements that would otherwise be impossible using traditional breeding.

The most important characteristic of genetic transformation lies in the fact that using this technique a single or a few genes can be transferred into an established genotype. Once a useful transformant is isolated (assuming stability of transgene expression) vegetative propagation, the normal method of multiplying fruit trees, provides unlimited production of the desired transgenic line. Fixation through the sexual cycle is unnecessary and inconvenient if commercially accepted cultivars are transformed.

2. DEVELOPMENT OF TRANSGENIC PEACHES AND NECTARINES

2.1 Methods Employed

There are many different techniques that allow the insertion of genetic material into plant cells and these can be divided into two main categories: direct (electroporation, microinjection, ultrasounds, liposomes, biolistic) or nondirect (*Agrobacterium* spp., viruses) with this latter technique requiring a living vector.

In peach, the only techniques used until now are biolistic (Ye *et al.*, 1994) and *Agrobacterium tumefaciens* (Hammerschlag *et al.*, 1989; Scorza *et al.*, 1990; Smigocki and Hammerschlag, 1991; Pérez-Clemente *et al.*, 2004).

The biolistic technique or DNA bombardment consists of shooting DNA coated micro particles (gold or tungsten) into plant tissues (Sanford, 1990). In the nuclei, the DNA can be inserted into

the genome by recombination. One disadvantage of this method lies in the fact that it is very aggressive and damages tissues. This can dramatically reduce regeneration. Also, it is not very efficient because the probability of the DNA insertion into plant chromosomes by recombination is low.

The method most utilized for the introduction of foreign genes into plant cells and the subsequent regeneration of transgenic plants is *A. tumefaciens* mediated. *A. tumefaciens* has the exceptional ability to transfer a particular DNA segment (T-DNA) of the tumor-inducing (Ti) plasmid into the nucleus of plant cells where it is then stably integrated into the host genome and transcribed. In the natural state, this process causes crown gall disease (Nester *et al.*, 1984) but for plants genetic engineering the disease-causing genes are removed from the plasmid. Gene transfer from the bacteria to the plant is a complex process and, using genetic engineering, *Agrobacterium* can be used to transfer any foreign gene (see review, de la Riva *et al.*, 1998).

2.2 Transgenes: Designing and Traits

Correct expression of the transgene is important for producing a desired phenotype. Sometimes the introduced genes are bacterial genes such as *cry* genes from *Bacillus thuringiensis* (*Bt*) and normally the eukaryotic cells cannot properly express them. So, it is necessary to modify the regulatory sequences. The most important regulatory sequence is the gene promoter, but also the terminator.

The most commonly used promoters reported are the constitutive promoters 35S, from the cauliflower mosaic virus (CaMV), and Nos, from *Agrobacterium* spp. with their respective terminators.

Alternatively, inducible promoters have been used. These are expressed in response to specific cues such as the presence of a substrate, pH level, or expression limited to a specific tissue and/or stage of development. In apple, for example, there are some advances with the use of tissue specific promoters (Gittins *et al.*, 2000, 2001).

Another constitutive promoter often used is the *Ubiquitin 1* promoter from corn (*Zea mays*). Besides its moderate constitutive activity, heat stress-induced expression has been reported in monocots such as maize (Christensen *et al.*, 1992) and rice (Takimoto *et al.*, 1994).

The dominant traits of commercialized transgenic plants are herbicide tolerance and *Bt*-based insect resistance (James, 2005). The traits introduced in fruit trees have for the most part been related to pest and diseases resistance (see review, Petri and Burgos, 2005). Currently, the only transgenic fruit tree that has been commercialized is papaya (*Carica papaya* L.) resistant to PRSV (papaya ringspot virus) (Fitch *et al.*, 1992; Lius *et al.*, 1997) (for further information about commercialized transgenic plants and their traits see www.agbios.com).

The only gene other than marker genes that has been successfully inserted into peach is isopentenyl transferase (*ipt*) from *Agrobacterium rhizogenes* (Smigocki and Hammerschlag, 1991). This gene is involved in cytokinin synthesis and produces transformed plants with increased branching (Medford *et al.*, 1989; Smigocki and Owens, 1989).

2.3 Selection of Transformed Tissues: Marker Genes

In a transformation procedure only a few cells will stably incorporate the transgene(s). Marker genes allow for the recognition and selection of transformed cells (Miki and McHugh, 2004). These marker genes are introduced with the gene of interest. There are two different classes of marker genes: selection and reporter genes.

2.3.1 Selection marker genes

These confer an advantage to the transformed cells in presence of a selective agent. The most common selective agents are antibiotics or herbicides.

The most common selectable marker gene, and used in *Prunus* almost exclusively, is neomycin phosphotransferase (*nptII*). This gene confers resistance to aminoglycoside antibiotics, like kanamycin, inactivating the phytotoxic antibiotic by phosphorylation.

In *Prunus*, there are a few reports of the use of other selection marker genes. These include hygromycin phosphotransferase (*hpt*) (Dolgov and Firsov, 1999) and the herbicide “Basta” resistance gene (*bar*) (Druart *et al.*, 1998). Selection in which nontransformed cells are inhibited from growing or killed is termed “negative selection” versus

“positive selection” in which transgenic cells can metabolize substances in the medium such as mannose for growth while untransformed cells cannot (Sigareva *et al.*, 2004). In peach, there is only one report of a positive selection-based protocol. In this case, using a media without cytokinins, the *ipt* gene acted as a selective marker gene and only the transformed cells were able to undergo organogenesis (Smigocki and Hammerschlag, 1991).

Theoretically, if the inhibitory concentration of a determined selective agent for any cultivar and any tissue is established, its addition to the medium should allow for the selection of the transformed cells and inhibit the development of nontransformed cells in the case of negative selection. However, sometimes the addition of the selective agent in the inhibitory concentration is prejudicial to the regeneration of transgenic plants and the timing of exposure and a stepwise increase in selective agent concentration is necessary. In these cases, it is necessary to establish an efficient selection strategy.

In *Prunus*, early selection, immediately following co-cultivation with the agrobacteria, has been used successfully (Gonzalez-Padilla *et al.*, 2003; Pérez-Clemente *et al.*, 2004; Song and Sink, 2006) but sometimes only a late selection or a progressive selection has allowed regeneration of transgenic plants (Scorza *et al.*, 1994, 1995b; Miguel and Oliveira, 1999; Yancheva *et al.*, 2002; Ramesh *et al.*, 2006). It has been suggested that massive necrosis in nontransformed tissues, which may occur under high selection pressure, could inhibit regeneration even from transformed cells (Szankowski *et al.*, 2003).

2.3.2 Reporter genes

These genes confer a trait that allows for identification of transformed cells or tissues. They encode enzymes that have chromogenic, fluorogenic, luminescence, or radioactive substrates, making it possible to visually identify the transformed cells.

The most commonly used reporter gene is β -glucuronidase (*uidA* or *gus*) isolated from *Escherichia coli*. This enzyme hydrolyses β -glucuronides (Jefferson *et al.*, 1987). A blue precipitate appears in the transformed cells after the incubation of the tissue with the substrate

5-bromo-4-chloro-3-indolyl- β -D-glucuronide (X-Gluc). Other substrates such as X-Gal or 4-MUG can be used to determine the activity of this enzyme.

Currently, most laboratories report the use of a chimeric version of *uidA* containing a plant intron that avoids gene expression by *Agrobacterium* eliminating false positive assays (Vancanneyt *et al.*, 1990).

Another reporter gene that has been used is the green fluorescent protein, *gfp* (Chiu *et al.*, 1996). Several *gfp* versions exist, but *sgfp* is the one has been used in *P. persica* (Pérez-Clemente *et al.*, 2004; Padilla *et al.*, 2006). The *sgfp* gene protein product fluoresces under blue light (optimum at 490 nm). The maximum fluorescence peak is at 509 nm and it has a secondary one at 540 nm (Elliot *et al.*, 1999). This protein is a modification from the original by changing a serine by a threonine in the 65 position, producing a 100-fold higher fluorescence than the wild-type protein (Chiu *et al.*, 1996).

The major advantage of green fluorescent protein (GFP) versus GUS lies in the fact that GFP detection is a nondestructive procedure and fluorescence can be measured *in vivo*. GUS assays cause death of the analyzed cell.

2.4 Regeneration of the Whole Plant (State of Art in Peach)

The lack of adventitious regeneration systems is the major limiting factor preventing the development of gene transfer technologies for fruit trees, especially in peach. Although regeneration protocols from different peach tissues have been reported (Hammerschlag *et al.*, 1985; Mante *et al.*, 1989; Pooler and Scorza, 1995; Gentile *et al.*, 2002), there are only a few reports of transgenic peach plant regeneration (Table 2).

Ye *et al.* (1994) optimized biolistic parameters for this specie. They obtained 65 putative transformed lines, 19 of these produced shootlike structures. Bombardment was applied to different tissues, but transformation was stable only from embryo-derived calli. With the other tissues only transient expression was obtained.

Peach has been shown to be amenable to *A. tumefaciens*-mediated transformation (Scorza *et al.*, 1990). Zimmerman and Scorza (1996)

^(a)Transformation efficiency (nonspecified by authors when not written)

reported on the success of a procedure combining biolistics and *A. tumefaciens* for the transformation of tobacco meristems and the production of transgenic plants. However, when tested on peach a significant mortality rate was encountered due to the mechanical damage and desiccation during dissection to expose the meristems. Also bacteria growth was difficult to control Scorza *et al.* (1995a).

An interesting procedure utilizing a “shooty mutant” strain of *Agrobacterium* was reported in peach (Smigocki and Hammerschlag, 1991). This strain carries a Ti plasmid with a functional *ipt* gene but a Tn5 transposon-inactivated auxin biosynthesis (*iaaM*). The infection with a “shooty mutant” strain induces the development of tumors, from which transgenic shoot regeneration occurs. Peach tissues transformed with the *ipt* gene allowed selection of transformed shoots on a medium low in growth regulators, and were the first transformed peaches reported. *In vitro* assays of these plants demonstrated delayed senescence on cytokinin-free medium as compared with nontransformed controls. The resulting peach plants were shorter in stature than controls and one line exhibited greater branching (Hammerschlag and Smigocki, 1998) presumably due to the effect of expression of the *ipt* transgene.

The second report of transgenic peach plants is that of Pérez-Clemente *et al.* (2004). Using longitudinal mature embryos slices as the explant source they regenerated several transgenic plants expressing the marker genes *nptII* and *gfp* with a transformation efficiency of $3.6 \pm 1\%$. This protocol improved upon the preceding report of Smigocki and Hammerschlag in that mature embryos are available year round while immature embryos are available for only a limited time each year. Both reports suffer from the fact that there are no publications successfully duplicating these techniques and producing transgenic peaches in other laboratories. Therefore, the general applicability of the methods is not established.

Although transformation of seed-derived material is of limited use for improving vegetatively propagated peach scion cultivars, it could have an impact on the development of new seed-propagated rootstock varieties, and also it allows for the introduction of novel genes into the peach germplasm and could be used in conventional breeding programs. The relatively rapid turn over

of peach varieties suggests the usefulness of seed-based transformation for peach improvement.

2.5 Specific Regulatory Measures Adopted

While genetic transformation or genetic engineering holds promise to allow for the targeted improvement of peach varieties and for the utilization of unique genes not otherwise available in peach germplasm resources, there are major difficulties to overcome in the utilization of this technology. Notwithstanding the two reports of transgenic peach production (a total of perhaps four plants), both regeneration of peach and gene transfer appear to be problematic. Additional research is needed in order to develop reliable transformation techniques. The absence of transgenic peach plants with improved traits of interest precludes a practical discussion of regulatory matters. Clearly, this will be a matter for the future. With that stated, it can be speculated that transgenic peach plants will perhaps require some regulatory considerations that differ from those required for field crops such as soybean, maize, and cotton. The deregulation of papaya ringspot virus resistant transgenic papayas in 1998 and perhaps the more relevant current work on the deregulation of a plum pox virus (PPV) resistant transgenic plum (*P. domestica* L.) variety (Scorza *et al.*, 2007) will provide some guidelines for the regulation of transgenic peaches. Under the current US regulatory framework three agencies exercise regulatory jurisdiction over the testing and commercialization of transgenic crops. The United States Department of Agriculture (USDA) Animal and Plant Health Inspection Service (APHIS) regulates the planting of genetical engineered (GE) plants. The US Food and Drug Administration (FDA) has jurisdiction over GE plants used as food. The US Environmental Protection Agency (EPA) regulates GE crop plantings of over 10 acres (a total of 10 acres over the entire United States) and regulates GE plants that produce molecules that protect plants against pests. Since peaches are a food crop and would be planted on over 10 acres GE peaches would be regulated by all three agencies. Nonfruiting ornamental or rootstock peaches might be regulated by APHIS and EPA only or by APHIS only if they did not contain genes whose products acted to control pests or diseases.

3. FUTURE ROAD MAP

3.1 Expected Products

Few peach cultivars show significant resistance or tolerance to pests and diseases, including devastating diseases such as sharka or PPV (Decroocq *et al.*, 2005). Sharka affects plums, peaches, and apricots producing losses in fruit quality and quantity and weakening infected trees. It is probably the most important disease in *Prunus*. Currently, the only control of the disease is removing infected trees and widespread application of insecticides against aphids. This heavy application of insecticides to reduce PPV dissemination in orchards can lead to the selection of aphid populations that are resistant to the pesticides, which makes sustainable management of fruit orchards difficult (Decroocq *et al.*, 2005). Isolation and incorporation into *P. persica* of sharka-resistance genes would be of significant economic and environmental benefit. Expression of viral proteins in transgenic plants may confer resistance against the virus. *P. domestica* hypocotyl slices have been transformed with the PPV coat protein gene (Scorza *et al.*, 1994) producing GE plum trees with high quality fruit that have maintained a high level of PPV resistance for over 8 years under field conditions of heavy infection pressure (Malinowski *et al.*, 2006).

Managing root diseases is a considerable challenge. Over 500 cationic membrane-acting proteins with antimicrobial and antifungal activities have been identified to date (Theis and Stahl, 2004). Recently, tobacco plants have been transformed with the gene of a monocot mannose-binding lectin *Gastrodia* antifungal protein (GAFP, *gastrodianin*) (Cox *et al.*, 2006). Transgenic plants showed resistance to fungi and also to nematodes. The introduction and expression of such genes in peach rootstocks could be very interesting in order to obtain rootstocks resistant to important diseases such as PTSL or oak (*Armillaria*) root rot. Plums (*P. domestica*) transformed with GAFP showed increased resistance to *Phytophthora* root rot (Schnabel *et al.*, 2007).

In peach, the extension of the ripening period is an important objective. In tomato, fruit ripening has been delayed expressing antisense genes in the plant (Gray *et al.*, 1992). This system partially blocks or delays fruit ripening. In the peach

cultivar “Redhaven” three complementary DNAs (cDNAs) coding for different endo- β -1,4-glucanases, enzymes involved in fruit ripening and softening, have been reported (Trainotti *et al.*, 1997). Lester *et al.* (1996) and Callahan *et al.* (2004) reported on the role of endopolygalacturonase genes in producing melting and nonmelting flesh types. 1-aminocyclopropane-1-carboxylate (ACC) oxidase is one of the enzymes responsible for regulating the expression of ethylene, which is active in promoting fruit ripening and softening. The ACC oxidase gene has been sequenced and cloned. Transgenic plums with the peach antisense ACC oxidase gene were obtained and, for some lines, ethylene production and fruit softening were delayed (Callahan and Scorza, 2007). The manipulation of these genes and other genes involved in peach fruit ripening and softening through antisense or gene silencing technologies and perhaps utilizing inducible promoters to control the timing of expression could provide for tree ripe fruit in the market, which is desired by consumers, with firmness sufficient for handling and storage.

Climate changes are now seen to pose potential problems for agriculture, as most temperate plants are exquisitely sensitive to their environment. Peach trees adapt to the short days and cold winter temperatures through the process of dormancy and resume growth as long days and warm temperatures return. Knowledge of and the ability to manipulate genes important in these adaptive processes may be critical in the future for improving the adaptation of particular peach cultivars or germplasm. The evergrowing (*EVG*) gene (Rodriguez-A *et al.*, 1994), which is sensitive to and regulates responses to the environment (day-length), has been cloned and sequenced (Bielenberg *et al.*, 2004). The effects of this gene, as it is manipulated in transgenic plants, on growth and development and responses to the environment, are currently under investigation (R. Scorza, personal communication).

3.2 Addressing Risks and Concerns

The two major concerns surrounding GE peaches would focus on human health and the environment. The effects on human health would be directly related to the particular gene engineered into peach and its established record of safety or

the lack of safety data. It is difficult to imagine that a gene product such as a known allergenic protein would be engineered into peach and it is difficult to imagine that such an engineered peach would be approved for release. Therefore, the establishment of safety would focus on those genes and the proteins that they produce that are not normally part of the human diet, directly or indirectly. Humans consume a vast array of genetic material and proteins that sustain a healthy life. For example, viral-derived nucleotide sequences in a GE peach whether expressed as RNA, protein, or present only as nucleotides may, on the surface, not be considered part of the human diet yet viruses, their genetic material and the proteins that they produce are consumed on a regular basis in virus infected crops (Bradford *et al.*, 2005). Several of the most commonly used marker genes, such as *NPTII* and *GUS*, have been approved for use in foods in the United States (59 Federal Register 49353, Sept. 28, 1994 and 66 Federal Register 42957-42962, August 16, 2001). GE crops containing virus- and/or insect-derived genes and marker genes have been approved and are currently in the market (www.agbios.com). GE peaches may also be developed containing transgenes derived from genes already found in peach or closely related, sexually compatible species. There is no established difference in safety between GE plants containing, as a class, transgenes derived from the transgenic species or its relatives, or GE plants containing transgenes from unrelated species or phyla. Currently, GE plants are evaluated for safety on an event basis that considers the species transformed, the gene, gene construct, and particular insertion event.

The ecological or environmental risks of GE crops are related to their potential for weediness and their effects on nontarget organisms and how these effects might upset the ecological balance. Peaches are not considered a weedy or invasive species and the likelihood of a GE peach becoming weedy appears to be remote. The effects of a transgenic peach on nontarget species such as beneficial insects would be a function of the specific transgene and the protein that it produces and under current regulations in the United States and other countries would be evaluated on an event basis. The fact that peaches generally do not spread beyond the orchard, are not native in much of the world, and do not naturally produce fertile

hybrids with many other *Prunus* species suggests the potential for negative ecological impacts of GE peaches is minimal.

3.3 Expected Technologies

The improvement of peaches through gene transfer utilizing those gene transfer technologies currently available will rely on the development of efficient transformation and regeneration protocols. Without critical breakthroughs in these areas peach improvement through gene transfer will be thwarted. Currently, the most promising systems for peach appear to be seed based. These systems are not ideal because while they will allow for the addition of novel traits such as PPV resistance into peach germplasm and this germplasm can be used in traditional breeding programs, seed-based systems do not allow for the improvement of existing cultivars. Ideally, genotype-independent procedures will be developed. These may be based on the transformation of meristematic cells with high regeneration potential and or the use of regeneration-promoting genes (Petri and Burgos, 2005).

To date, there is only one report showing adventitious regeneration in peach using somatic tissues (leaves) but the regeneration rates were still low, 28.3 ± 1.7 the highest, and it was limited to a few genotypes (Gentile *et al.*, 2002). Although, it has been tried before unsuccessfully (Scorza *et al.*, 1995a), efficient meristem-transformation protocols could possibly resolve the genotype problem because *de novo* adventitious bud regeneration would not be required and this process appears to be highly genotype dependent.

Transformation of antibiotic-sensitive species, like peach, may be improved by using positive selection based on providing the transformed cells a metabolic advantage rather than in killing nontransformed cells (Joersbo, 2001). Recently, the use of a positive selection in almond resulted more efficient than the usual negative selection with kanamycin (Ramesh *et al.*, 2006).

The marker genes are another obstacle. The public concern with the introduction of antibiotic resistance into foods and the restrictions imposed by European Union mandates that do not allow deliberate release of plants transformed with antibiotic resistance genes and their commercialization (Directive 2001/18/EEC of the European

Parliament and the Council of the European Union), will place a priority on the development of methods to avoid the use of antibiotic selection or to allow elimination of marker genes from transformed plants postselection.

3.4 Specific Details for Intellectual Property Rights (IPR), Public Perceptions, Industrial Perspectives, Political and Economical Consequences

The application of genetic engineering to peach holds many of the same promises for genetic improvement in common with other species (biotic and abiotic stress resistance, growth control, improved fruit quality, etc.). GE peaches will also be affected by the same IPR issues, regulatory constraints, and public perceptions. As GE peaches enter into testing concerns related to gene flow, nontarget effects, and food safety must be addressed. Long-term field evaluation of the stability of the engineered trait will be necessary. All of these issues will be compounded in breeding programs and will affect the level and rate of progress that can be achieved. If GE technologies are to be realistically utilized then the genetic improvement of peaches and other fruit species must be undertaken by genetic improvement programs composed of scientists trained in classical and molecular breeding working as teams and with long-term institutional support.

Plums

Ann M. Callahan

Appalachian Fruit Research Station, USDA-ARS, Kearneysville, WV, USA

1. INTRODUCTION

1.1 History, Origin, and Distribution

The word plum is derived from the word “plume” (old English), which is a modification of *prunum* (Latin) or *prounmom* (Greek) (Merriam-Webster Dictionary). It represents over 50 different species of *Prunus* that bear small fruits, which are generally larger than cherries and are unique relative to cherries by the presence of a suture on one side, no terminal bud, and a relatively flat stone. Plums can be differentiated from peaches by the lack of a terminal bud, multiple flowers from a bud, and an elongated pedicel (Okie and Weinberger, 1996). Plum trees are grown mainly for their fruits, which come in a variety of colors and shapes, and are used as *Prunus* rootstocks and as ornamentals. Their origins have been traced to three different continents, Europe, Asia, and North America, and they appear to have been domesticated very early (Okie and Weinberger, 1996; Faust and Suranyi, 1999).

The European plums, which are primarily used as dried plums (formerly known as prunes), are thought to have originated in the area between southern Europe and Asia Minor (Cullinan, 1937; Crane and Lawrence, 1952). Stones from *Prunus insititia*, *Prunus domestica*, *Prunus spinosa*, and *Prunus cerasifera* hybrids have been found in archeological digs dated as early as the Neolithic age (4000–2500 BC) in Germany, Ukraine, and Poland, and late Neolithic age (2500 BC) in Switzerland, Germany, Austria, and Cyprus, and the Bronze/Iron age (1400 BC) in England (Faust

and Suranyi, 1999). They were thought to be cultivated by the Assyrians and then bred by the Romans. Writings with mentions of plums are found from 7th century BC (reviewed in Faust and Suranyi, 1999) including writings of Archilochus, Xenophon, Vergil, Horace, and Ovid. Plums were well established as a cultivated fruit crop in Roman times and plums of various characteristics are mentioned in Pliny the Elder’s (1st century). Many types of plum stones were found in Roman archeological excavations all over Europe, and appear to have been planted wherever Roman armies had been (reviewed in Faust and Suranyi, 1999). A second wave of plum establishment in Europe followed the Crusades and by the Renaissance and later various plums were imported and grown all over Europe. Types, such as the Prune d’Agen (*P. domestica*), were named after the town of Agen in France where the plum resided in the monastery garden. “Reine-Claude” (*P. domestica*), which was introduced to France from Italy and named for Queen “Claude”, represents the “green gage” plums. The name “gage” comes from a single surviving plum sent to the “Gage family” in England from a monastery in France.

The Japanese plums, primarily used as fresh fruit, are represented by *Prunus salicina* Lindl. and *Prunus simonii* Carr. actually originated in China. *P. salicina* originated in the Yangtze river basin and *P. simonii* is from northern China. The history of one cultivar, “Zhui Li” (*P. salicina*), can be traced over 2000 years. Plums were brought to Japan a long time ago as plum stones have been found in archeological excavations in Japan dated

to the Yayoi Era or 300 BC. Plums have also been mentioned in Japanese literature and poetry as early as 750–800 AD. It is not clear though if it is a true plum or *Prunus mume*, an apricot (Okie and Weinberger, 1996; Faust and Suranyi, 1999).

The last group, the North American plums, is used as dried, cooked, or fresh fruit. There are many species including *Prunus americana* Marsh., *Prunus angustifolia* Marsh., *Prunus hortulana* Bailey, *Prunus maritima* Marsh., *Prunus nigra* Ait., and others. When Europeans came to North America, the native Americans had already cultivated plums, but most of the species are found only in small areas with the exception of *P. angustifolia* Marsh. Only a few plum stones have been found in archeological excavations, one dated from 250 BC to 400 AD and a second in Arkansas from the 1st to 5th century. A number of American plums were selected and propagated during the 1800s including “Miner”, *P. hortulana*, from Alabama and “Wild Goose”, *Prunus munsoniana* from Tennessee (Okie and Weinberger, 1996; Faust and Suranyi, 1999).

Plums originated in three distinct areas of the world, and breeding and crossbreeding took place mainly in the European plums as people moved back and forth throughout Europe and Eurasia. As people came to North America, plums spread out. Writings mention that European plums, Damsons, were brought from England and France in the late 1600s to New England and Canada and later to North Carolina. In the late 1700s plums were mentioned in nursery catalogs including plums described as greengage and egg plums. Orchards and nurseries offered both the European plums and American plums. In 1856, the “Prune d’Agen” plum was brought to San Francisco and established in a nursery in the Santa Clara Valley and in commercial orchards. Production was increased with the introduction of *P. cerasifera*, myrobalan, as a rootstock (Okie and Weinberger, 1996; Faust and Suranyi, 1999). This was the beginning of the California dried plum industry.

Japanese plums were brought to the United States in 1870 to Vacaville, California, and introduced into commercial orchards there. Luther Burbank established a breeding program with Japanese plums as well as American plums. In 1885, he imported a plum, “Blood Plum of Satsuma”, which had a red flesh that he used to produce a cultivar known as “Santa Rosa”, which

was thought to be the result of hybridization between *P. simonii* and *P. americana*. This along with other releases formed the basis of the California “Japanese” plum industry (Dreyer, 1985; Byrne, 1989; Okie and Weinberger, 1996; Faust and Suranyi, 1999). Burbank was awarded one of the first plant patents, no. 12, for one of these releases.

1.2 Botanical Description

Plum was first used to describe any dried fruit. Now it represents a number of different species, all from the division Magnoliophyta, class Magnoliopsida, order Rosales, family Rosaceae, genus *Prunus* L. The genus has been divided into seven subgenera based on how the leaves in buds are rolled, flower characteristics, and various characteristics of the fruit following a scheme of Strasburger (OECD, 2002). The subgenus *Prunus* includes the European and Japanese species, such as *P. domestica*, *P. salicina*, *P. cerasifera*, and the North American species, such as *P. americana* and *P. nigra*.

Plums are typically small- to mid-size trees, the Japanese plum trees being somewhat smaller and less upright than the European ones (<http://www.uga.edu/fruit/plum.html>). The Japanese trees are also more disease resistant, have a shorter juvenile period, and more abundant blooms. Bloom time for the Japanese varieties is earlier, which makes them more susceptible to spring frosts. Japanese varieties require cross-pollination while approximately half of the European plums are self-fertile. Commercially, all plums are grown on rootstocks of which many different species are used including *P. cerasifera* (myrobalan) and hybrids with native American plums.

Plum fruit is classified as a drupe and tends to be round in Japanese plums and more oval in the European plums (<http://www.uga.edu/fruit/plum.html>). The fruit takes between 2 and 6 months to ripen in European plums while only about 3 months in the Japanese plums. The fruit is also handled differently because of the high sugar/soluble solids of the European fruits; they can remain on the tree until they attain 25–35% sugar and then can be stored for long periods. The Japanese plums are more like peaches in that they are harvested earlier and have a limited

storage life of up to 2 weeks before they need to be consumed.

Like other *Prunus*, the base chromosome number (x) is 8, with a majority of the Japanese and North American species, including *P. salicina* and *P. cerasifera* being diploid with a chromosome number of $2n = 2x = 16$. *P. spinosa* L. is tetraploid having 32 chromosomes and *P. domestica* is hexaploid with 48 chromosomes (OECD, 2002). Table 1 lists a number of plum species, their distribution, and chromosome numbers.

The major commercial species of plum—*P. domestica* and *P. salicina*, as well as *P. americana*, *P. simonii*, *P. syriaca*, and *P. italica*—are not found

in the wild, suggesting that they were cultivated very early in three different areas (OECD, 2002). This presents an interesting riddle as to their origin and relationship to existing wild species. There is much speculation especially on the origin of the hexaploid *P. domestica* as well as the contribution of different species to many of the modern cultivars. It has been postulated (Crane and Lawrence, 1952) that *P. domestica* (hexaploid) was the result of a combination of *P. cerasifera* (diploid) and *P. spinosa* (tetraploid). This was based on the chromosome numbers; the fact that *P. cerasifera* and *P. spinosa* grow in the same region in the Caucasus, that triploids could be found in

these species, that one could obtain a hexaploid from a cross between these species, and that the variation in fruit ground color and anthocyanins in *P. domestica* could be accounted for by the additive properties of *P. cerasifera* and *P. spinosa*. Zohary (1992) disputed those arguments because the generation of the hexaploid was not followed up to determine how the chromosomes paired and how it crossed to *P. domestica*. It appeared that variation in *P. cerasifera* could be the predecessor as there was much more phenotypic variation and geographical locations, which overlapped with other *P. domestica* varieties. In addition, crosses between *P. domestica* and *P. cerasifera* resulted in some stable tetraploids implying that the chromosomes were balanced. Reynders-Aloisi and Grellet (1994), from restriction fragment length polymorphism analyses of ribosomal RNA genes, suggested that *P. domestica* originated through polyploidization of *P. cerasifera* and not from *P. spinosa*. Resolving the origin of *P. domestica* could help us not only to understand how the various species evolved but also to identify broader germplasm crosses that might yield promising traits. The development of techniques that differentiate isozymes, and now molecular markers to determine polymorphisms among species and even among cultivars, have allowed a new look into the relationships of the diverse plums.

Mowrey and Werner (1990) studied genetic similarity among 34 species of *Prunus* using 11 isozymes. As expected, most of the European, Japanese, and the American plums clustered into three distinct groups. But between the American and European plums two cherry species were grouped. Those two species, *Prunus besseyi* and *Prunus pumila*, have been reported to cross-hybridize with plums, yielding fertile F_1 progenies. Two American plums, *Prunus umbellata* Ell. and *Prunus maritima* Marsh., grouped closer to the Japanese and European plums than to the other American plums or cherry. This suggested that they might have come from a European introduction to North America (Mowrey and Werner, 1990).

Random amplified polymorphic DNA (RAPD) markers were used to group plums in general, determine species composition, and distinguish cultivars as well as rootstocks (Bellini *et al.*, 1998; Casas *et al.*, 1999; Shimada *et al.*, 1999; Boonprakob and Byrne, 2003; Liu *et al.*, 2006).

These groups found similar results in that the Japanese species grouped together as did the European species. In a rootstock study (Casas *et al.*, 1999), *P. insititia* grouped amongst *P. domestica* cultivars suggesting a common ancestry as was suggested by Crane and Lawrence (1952) that both the hexaploid species were derived from *P. spinosa* and *P. cerasifera*. Bellini *et al.* (1998) found that *P. cerasifera* Ehrh grouped within the *P. domestica* suggesting that *P. cerasifera* could have been an ancestor as suggested by Crane and Lawrence (1952). Shimada *et al.* (1999) found that *P. cerasifera* and *P. spinosa* grouped with *P. domestica* but were genetically distinct suggesting that more markers were needed to determine how closely related they were to *P. domestica*. Shimada *et al.* (1999) also suggested that the “Burbank” Japanese plum releases that were purported to have North American plums as ancestors grouped with the Japanese plums and even between Japanese and European plums but not with the North American plums. Boonprakob and Byrne (2003) confirmed the analyses of the “Burbank” Japanese plum founding clones and concluded that “Mariposa” and “Gaviota” were derived from *P. salicina* and *P. simonii* with maybe some *P. cerasifera*, and “Santa Rosa” and “Eldorado” were derived from all three species. Liu *et al.* (2006) suggested from their use of RAPDs that *P. simonii* is possibly a variant of *P. salicina* rather than a species, and even though *P. cerasifera* and *P. spinosa* are related to the European plum group it is unlikely that *P. domestica* originated from a hybrid of these two species.

Amplified fragment length polymorphism (AFLP) and intersimple sequence repeat analyses provided more molecular markers to differentiate species (Goulao *et al.*, 2001; Aradhya *et al.*, 2004). These separated the Japanese plums from the European plums. In addition, Aradhya *et al.* (2004) was able to group *P. cerasifera* separate from *P. domestica*. In an even finer analyses using microsatellite markers (Ahmad *et al.*, 2004; Rohrer *et al.*, 2004), the North American species grouped as expected with the exception that the more widely dispersed cultivars of *P. americana* did not group together but interspersed with the other North American plums (Rohrer *et al.*, 2004). Ahmad *et al.* (2004) separated apricots, Japanese plums, pluots, and plumcots. The plumcots were between the plums and apricots while the pluots were grouping with the plums.

Molecular markers, RAPDs and AFLPs, and now simple sequence repeats, have helped to determine the source of the modern germplasm with the goals of expanding the germplasm. Because of the ease in which many of the diploid species are able to cross-hybridize, background has always been a little unsure. One of the mysteries that remain has been how the hexaploid species *P. domestica* arose. It had been postulated that since no hexaploid species were found resembling *P. domestica* it must have come from the hybridization of a *P. spinosa* and a *P. cerasifera*. Recent evidences also do not support this idea. It appears from marker analyses that *P. domestica* is not closely related to *P. spinosa* and may more likely be the result of hybridization between different ploidy numbers of *P. cerasifera*. There has also been a report of a hexaploid plum that resembles *P. domestica* found in China. The marker analyses have also been helpful in determining the makeup of several of the Japanese plums that appear to be the result of interspecific breeding.

1.3 Economic Importance

Plums are grown in temperate zones worldwide. There is a fresh fruit market, a dried fruit market, and an emerging juice market. China is by far the largest grower of plums with over 4.6 metric tons of fruit in 2005 worth approximately one billion US dollars with Serbia and Montenegro a distant second with 0.5 metric tons of fruit worth about 140 million US dollars. The biggest exporter of fresh plums is Chile with a value of 76 million US dollars. The United States is the biggest exporter of dried plums with a value of 135 million US dollars. Table 2 presents a list of the top 20 countries in plum production, exports, and imports (FAOSTAT, 2000/2004/2005). It may be noted that several countries have a decline in production (in bold font), most notably the United States. Table 3 lists the area in hectares of plums that are harvested from the top 20 plum producing countries for 2004 and 2000 (FAOSTAT, 2000/2004). Again the area reflects the yields with China having the largest area cultivated and the decrease in the United States' production with decreased acreage.

The two major uses of plums are as a fresh market product (*P. salicina*) and a dried

fruit product (*P. domestica*), both for direct consumption. There are many other uses; the most notable is for the production of a type of plum brandy known as slivovitz, Mirabelle, rakia, zwetschgenwasser, or quetsch. It is made from distilled fermented plums and contains a range from 20% to 75% alcohol. It usually is made with local varieties of *P. domestica*. In Serbia and Montenegro, the second largest producer of plums, 80% of the fresh market plums go into the production of slivovitz (Buric, 2003). Sloe plums or *P. spinosa* are used to flavor gin. Plums are also used for jams and jelly as well as dried for candy and baked goods.

Plums have always been desired for their taste, colors, and ease of drying without fermenting or spoiling. Table 4 lists the nutrient contents of a Japanese-type plum as well as a dried European plum (USDA, 2006). Dried plums have been well known for health related value, i.e., as a laxative (Tinker *et al.*, 1994; Stacewicz-Sapuntzakis *et al.*, 2001). (The marketing name of prunes has been changed to dried plums to dissociate that name with any negative connotations.) But, in fact, both fresh plums (Japanese) and dried plums (European) have health benefits. The fruits are all among the highest in antioxidant containing foods. In a top 20 list of foods containing antioxidants, dried plums ranked ninth, black plums ranked 16th, and plums, in general, ranked 19th (Wu *et al.*, 2004). In a study on several cultivars of plum as well as peaches, there was variability in the levels of various antioxidant compounds (Gil *et al.*, 2002). Cultivars with the darkest flesh and skin contain the most as predicted. There have also been a series of reports on the beneficial effects of dried plums on preventing the decrease in bone density associated with menopause or gonadal hormone deficient males (Franklin *et al.*, 2006).

1.4 Traditional Breeding

A successful cultivar is one that makes a profit for the grower. There are different ways to achieve this. One way is to have the fruit ripen at a unique time so that there would be less competition in the market at that time. Ideally, breeders would have a fruit with the same desired characteristics that ripens each week in the season. Another is to improve fruit quality in order to attract

Table 3 Amount of land in cultivated plums

more buyers. These qualities are size, shape, skin color, attractiveness of ground color, color of flesh, firmness, freeness of pit, texture, and fruit quality (flavor, sugar, acid, etc.) (Okie and Weinberger, 1996). A third way to improve profit is to lower production costs. This could come about by increasing disease and insect resistance, which could minimize chemical use, increase yields, and decrease inputs. Yields could be increased through having cultivars that are better adapted to a specific region as well as more highly productive trees. Decreasing inputs could come from a less vigorous tree that does not have to be pruned as much or a drought-tolerant tree needing less water. The bottom line is to be able to grow a tree and market desirable fruit at a profit.

Breeding programs for European plums have different goals depending on the location and market targeted. Collectively, these goals include shortened juvenility period, resistance to pests and disease (bacterial canker, silver leaf, and fruit rot), resistance to sharka, tolerance to abiotic stresses, adaptability to regional conditions, cold hardiness, semicompact tree size, late bloom, cross-fertility, changes in ripening time, increased productivity, maximized fruit set, large fruit size, red, purple, and blue color, higher fruit quality,

better flavors, higher sugar content, freestone, and long shelf life (Okie and Weinberger, 1996).

Breeding programs for Japanese plums have goals similar to that for European plums, and include disease resistance, cold hardiness, low chilling requirements, compact trees, improved productivity through better pollination, self-fertility, late blooming, specific ripening times, increased fruit size, black skin color (hide bruises), yellow skinned and other colors, red-fleshed plums for warm climates, better eating quality, firmness for shipping, and improved storage ability (4 weeks to transport by ship) (Okie and Weinberger, 1996).

Selection and classical breeding have been amazingly successful in generating a number of high-quality cultivars, which have then been adapted in individual breeding programs for the local areas they are grown in (reviewed in Ramming and Cociu, 1991; Okie and Weinberger, 1996; Okie and Ramming, 1999). Most of the European plums are derived from high-quality types, such as “Reine-Claude”, “Prune d’Agen”, “Italian”, and “Pozegaca”, which were selected hundreds of years ago but still are in the background of many cultivars. More recent introductions from breeding programs such as “Stanley” (1926, New York Agricultural Experiment Station), which has “Italian” background, have also been successful. In Japanese plums, more breeding has occurred through cross-species hybridization to yield cultivars that are able to adapt to different conditions, yet still the commercial markets are based on a limited number of old cultivars that were bred by Luther Burbank such as “Santa Rosa”, or directly from Japan such as “Burbank” and derivatives of those. Local adaptations of these cultivars provide most of the world’s commercial germplasm.

Rootstock breeding has taken a somewhat different approach in the utilization of interspecific hybrids as well as different species. The major rootstocks are derived from *P. domestica*, *P. cerasifera*, Marianna (*P. cerasifera* × *P. munsoniana*), and Peach (*Prunus persica*) (Ramming and Cociu, 1991; Okie and Weinberger, 1996). Improvements have been in “vigor, longevity, hardiness, nematode and disease resistance, dwarfing ability, tolerance to drought or flooding, compatibility and ease of propagation” (Okie and Weinberger, 1996).

New tools for breeding are becoming available. The first approach has been to develop genetic linkage maps of markers that are associated with

the traits of interest. These then can be used to screen seedlings for the traits of interest by their linkage to markers, or marker-assisted selection (MAS). In plum, these techniques have been used to identify molecular markers that are close to the *Ma* gene, which is responsible for conferring nematode resistance in *P. cerasifera* (Claverie *et al.*, 2004a; Dirlewanger *et al.*, 2004a). Again using these markers, the location of the *Ma* locus has been narrowed and the actual physical piece of DNA with the *Ma* locus has been isolated in a bacterial artificial chromosome clone (Claverie *et al.*, 2004b). This knowledge is being used in a breeding program to “stack”, that is, to combine several genes for nematode resistance in a *P. cerasifera* rootstock (Dirlewanger *et al.*, 2004c; Lecouls *et al.*, 2004). In general, this approach works well with the traits of interest that are clear in their scoring and segregation patterns. As general

Prunus molecular maps are further developed (Dirlewanger *et al.*, 2004b), their use in plum breeding will increase. Details on molecular mapping and breeding in plums can be found in a recent review by Esmenjaud and Dirlewanger (2006).

1.5 Limitations of Conventional Breeding and Rationale for Transgenic Breeding

Plums are represented by a wide variety of sexually compatible species that have a great deal of desirable traits, as well as undesirable traits (Ramming and Cociu, 1991). The existing germplasm used for both the European plum breeding programs (hexaploid) and the Japanese plum breeding programs (diploid) have been derived from limited germplasm. With the advent of marker-assisted breeding and larger general

Prunus maps to aid in introgressing desired traits from diverse germplasm into existing commercial cultivars (Dirlewanger *et al.*, 2004c; Lecouls *et al.*, 2004; Esmenjaud and Dirlewanger, 2006), what would be the reason for using transgenic breeding? The stock answer would be that transgenic breeding is needed (1) if a trait is not present in sexually compatible germplasm, or (2) if a trait is too closely linked to some essential trait to be separated through hybridizations, or (3) if only a single (or small number) trait is desired to be modified, i.e., not reassemble the traits as in a sexual hybridization.

One trait that would meet the first and third criterion for plum would be resistance to sharka disease. The biggest threat to the existing plum industry as well as the stone fruit industry is the devastating virus plum pox potyvirus (PPV), the causal agent of sharka (Dunez and Sutic, 1988; Nemeth, 1994). PPV is carried by aphids in a nonpersistent manner on their stylus and transmitted from tree to tree when the aphids probe (Kunze and Krczal, 1971). Grafting with infected budwood also transmits PPV. The symptoms of the infection include chlorosis of the leaves and fruit, hallmark rings on fruit, leaves, and even seeds, deformed fruit, reduced quality of the fruit, premature fruit drop and in the presence of other viruses, tree decline. PPV was first reported in Bulgaria during the World War I (Atanassov, 1932). It then proceeded to spread throughout Europe. By the 1990s, PPV had infected over 100 million stone fruit trees (Nemeth, 1994). It has now been detected outside of Europe in countries as far ranging as India (Thakur *et al.*, 1994), Chile (Rosales *et al.*, 1998), the United States (Levy *et al.*, 2000), and Canada (Thompson *et al.*, 2001). New reports have detected PPV in China, Pakistan, and Argentina (Navratil *et al.*, 2005; Dal Zotto *et al.*, 2006; Kollerova *et al.*, 2006). The only cure is to destroy the trees. In the United States, where there was only a limited outbreak in Pennsylvania, over 1400 acres were destroyed at a cost of 40.5 million US dollars.

Resistance to PPV is needed because if a tree were tolerant it would still be a source of inoculum for other trees. In looking for such a gene in sexually compatible species, it has been found that commercial stone fruit are not the only trees susceptible to PPV. In

laboratory tests over 30 different *Prunus* including *P. mexicana*, *P. maritima*, *P. angustifolia*, and *P. americana* exhibited susceptibility (Damsteegt *et al.*, 2004). There are reports of some natural resistance/tolerance to plum pox virus, but the terms resistance, tolerance, and immunity are not always consistent with each study, nor the isolate of PPV, making comparisons between cultivars difficult (reviewed in Kegler *et al.*, 1998). There are breeding programs specifically with the goal of at least PPV tolerance that have reported good success (Hartmann, 1998, 2002; Rankovic and Ogasanovic, 2000). Resistance reported in *P. domestica* appears to be through a hypersensitive response to PPV (Kegler *et al.*, 2001). While there are breeding programs with some promises of resistance, the necessity for plum cultivars to be locally adapted as well as high standards for fruit quality would necessitate that resistance be introduced in many lines to recombine all the traits necessary for a resistant commercial cultivar. This difficulty is what makes PPV resistance meet the third criterion for a transgenic breeding approach, i.e., a single trait that needs to be modified.

Genes for resistance to other viruses are potential targets for transgenic breeding for similar reasons that PPV resistance, is a target, though currently no other virus is as destructive as PPV. Lastly, a good use for transgenic breeding would be to change a single-gene expression pattern without rearranging the genes in a typical hybridization. An example would be to manipulate the keeping quality in all plums. One of the problems in our worldwide marketing is that to ship plums economically, it has to be done by boat, which means fresh market plums need to have a keeping life of about four weeks.

2. DEVELOPMENT OF TRANSGENIC PLUMS

2.1 Developing a Transformation System

An initial transformation system for *P. domestica* was developed using two different constructs (Mante *et al.*, 1991), pCGN7001 and pCGN7314 (Comai *et al.*, 1990). These contained a selectable gene, neomycin phosphotransferase, *NPTII*, from *Escherichia coli* (Rothstein *et al.*, 1980), driven by

a 35S cauliflower mosaic virus (CaMV) promoter region (Odell *et al.*, 1985) in one construct and by a mannopine synthetase, MAS, from *Agrobacterium tumefaciens*, promoter (Comai *et al.*, 1990) in the other construct. The gene of interest was the β -glucuronidase, *uidA* gene (*GUS*), from *E. coli* (Jefferson, 1987), driven by either the MAS promoter or a double 35S promoter and terminated by the MAS 3' end. The goal of the project was to establish a transformation system and to determine what promoters would be needed to detect activity of the gene of interest as well as the selectable marker.

Similar systems have been developed for *P. salicina*. Prieto *et al.* (2005) applied the system described above to *P. salicina* varieties using NPTII as the selective marker and green fluorescent protein (GFP) from the jellyfish *Aequorea victoria* (Davis and Vierstra, 1996) as a reporter gene.

Yancheva *et al.* (2002) reported the development of transformation system in *P. domestica* using leaf tissue. The vector used was based on pSM-GFP containing the GFP as a marker gene driven by 35S promoter and containing NPTII as a selectable marker.

Dolgov *et al.* (2005) and Mikhailov *et al.* (2007b) have also reported a transformation system using leaf tissue from *P. domestica*. Their vector was pNOV35S-GFP, having a redshifted *GFP* gene driven by the 35S promoter and a phosphomannose isomerase gene (*pmi*) (from *E. coli*) based selection (Joersbo *et al.*, 1998) driven by a promoter from cestrium yellow leaf curling virus (CMPS).

Transformation rates in plum have been low, ranging from less than 1% to approximately 4% at the highest. In one study, several different constructs and strains were tested to determine the most efficient parameters for transformation of *P. domestica* (Padilla *et al.*, 2003). Two different plasmid backbones, pBISNI (Narashimhulu *et al.*, 1996) and pGA482GG (An, 1986) were used, both containing NPTII as the selectable marker. Various genes of interest were used including the *PPV-CP*, *TomRSV-CP*, *PNRSV-CP*, *PDV-CP*, and peach antisense *ACO1*. Overall results suggested that the pGA482GG background results in more efficient transformation of *P. domestica*. Other studies that used leaf tissue changed the selection scheme as well as the vectors and *Agrobacterium* strain resulted in lower efficiencies (Yancheva *et al.*, 2002; Mikhailov and Dolgov, 2007).

2.2 Methods of Transformation

The method used for generating all the transgenic plums has been by transformation with *Agrobacterium tumefaciens*. Mante *et al.* (1991) first devised a method for transforming plum hypocotyls. Basically an overnight culture of *Agrobacterium* (EHA 101) was grown at 28 °C in Luria broth medium with both kanamycin (50 mg l⁻¹) and gentamycin (100 mg l⁻¹), and then was concentrated to 10⁵–10⁶ cells ml⁻¹ of murashige and skoog (MS) liquid medium. The freshly cut plum hypocotyls were co-cultivated with 10⁶ cells in 10 ml of liquid shoot regeneration media (SRM) for 48–72 h, then washed and cultured for 6–10 days with carbenicillin and cefotaxime. Variations of this procedure have been used in all the transformation protocols, with variations on *Agrobacterium* concentration, co-cultivation time, strain used (EHA101, EHA105, C58/Z707, LB4404), and antibiotics used to kill the *Agrobacterium*. Reported transformation rates range from less than 1% to 4% (Padilla *et al.*, 2003).

The method reported for transformation of leaf tissue began with adventitious shoots induced from plum leaf using 5 mg l⁻¹ BAP (6-benzylaminopurine) and 0.5 mg l⁻¹ IBA (indole-3-butyric acid), modified to 2 mg l⁻¹ BAP and 0.1 mg l⁻¹ IBA. The youngest leaves were wounded, then exposed to the bacteria for 30 min. Following a 3-day co-cultivation in the dark, the leaves were induced to form shoots with 5 mg l⁻¹ BAP, 0.5 mg l⁻¹ IBA in the presence of cefotaxime for 10 days in the dark. The shoots were then transferred to media with mannose or hygromycin to select for the transformed tissue with the *pmi* gene and *hpt* gene, respectively. After several months, shoots and cali that survived were placed on micropropagation media with selection and rooted. Transformation rates were approximately 1.5–2.2% (Mikhailov and Dolgov, 2007; Mikhailov *et al.*, 2007a, b).

2.3 Selection of Transformed Tissue

Most of the constructs used in plum transformation contain the *NPTII* gene for selection using kanamycin. One of the difficulties in *Prunus* transformation has been the low rate of regeneration (see Section 2.4), and one of the

effects of kanamycin is slow growth. Several of the successful transformation experiments have varied timing of kanamycin selection. In Mante *et al.* (1991) selection using kanamycin at 75 mg l^{-1} took place 6–10 days after co-cultivation. Levels of $10\text{--}75 \text{ mg l}^{-1}$ of kanamycin were reported to cause control tissue to remain white, not to expand and not to produce shoots. Yancheva *et al.* (2002), in their leaf system, used a low level of selection (25 mg l^{-1}) immediately following co-cultivation resulting in a large number of “escapes” or clones that were not transgenic. To remedy this but still have good growth, the first cycle of selection was at 25 mg l^{-1} and the second round was at 50 mg l^{-1} . The study of Padilla *et al.* (2003) used two different selection strategies. The first was to place the hypocotyls sections on 80 mg l^{-1} kanamycin immediately following co-cultivation. This was compared to delaying the addition of kanamycin for 2 weeks. The late selection resulted in approximately the same number of transformed lines as the early selection but with more “escapes” than the earlier selection.

Two other selection schemes have been used with success, a gene for phosphomannose isomerase, *pmi*, that allows for plant growth on mannose, and a hygromycin phosphotransferase gene, *hpt*, that allows for plant growth on hygromycin (Mikhailov and Dolgov, 2007; Mikhailov *et al.*, 2007a, b). The mannose selections were difficult because transgenic tissue allowed nearby escapes (Mikhailov *et al.*, 2007a), which could be avoided by passaging on selective media but overall transformation rates were low ($>0.1\%$, $n = 1$). In comparisons of transformation rates resulting from early (3 days) and late (13–14 days) selection on hygromycin, the late selection had significantly higher transformation rates, 2.2% versus 0.27% (Mikhailov and Dolgov, 2007).

2.4 Regeneration of Whole Plants

Regeneration efficiency appears to be the key to successful transformation and appears to be a stumbling block for transformation of plum. The first breakthrough came in the 1989 (Mante *et al.*, 1989) in which thidiazuron, N-phenyl-HN-1,2,3-thidiazol-5-ylurea (TDZ), was used to induce plant regeneration from mature cotyledons in *P. domestica*. The basic protocol

that evolved from these studies (Mante *et al.*, 1991) used seeds from cold storage rather than freshly harvested seeds. The hypocotyls were sliced from mature cotyledons that had their embryonic axes removed, and placed on MS medium with $2.5 \mu\text{M}$ IBA and $7.5 \mu\text{M}$ TDZ. Shoots developed by 4 weeks, and these were transferred by 10 weeks to rooting media with $2.5 \mu\text{M}$ IBA in the light. In the case of transformed hypocotyls, shoots were transferred every 4 weeks on selective media for a total of five transfers before transferring to rooting media. Acclimation to soil and the greenhouse was a 2-week process in a 1:1 mixture of peat moss:perlite mix. Overall rates were approximately 60–80% of cotyledons producing shoots, only 20–25% rooted and approximately 90% were successfully acclimatized in the greenhouse. Several improvements have been made with the initial IBA level reduced to $0.25 \mu\text{M}$, the multiplication step for transformed shoots has been modified by transferring them to media with $0.2 \mu\text{M}$ IBA and $5 \mu\text{M}$ BA, and the efficiency of rooting was improved to 50% by dipping the shoots in $2500 \mu\text{M}$ IBA before placing them on media with $0.01 \mu\text{M}$ kinetin and $0.01 \mu\text{M}$ naphthalene acetic acid (Scorza *et al.*, 1994). Several changes have since been made to simplify the protocol (Padilla *et al.*, 2003). This involved the composition of the regeneration media, the substitution of $1\text{--}3 \mu\text{M}$ benzyl-aminopurine for IBA in the proliferation media, a shorter time on the regeneration media, and an increased level of α -naphthaleneacetic acid (NAA) to $5 \mu\text{M}$ in the rooting media allowed the IBA dip to be eliminated (Padilla *et al.*, 2003). The transfer of plantlets to soil in the greenhouse was also modified by leaving the plantlets in soil in the culture room to acclimatize before moving to the greenhouse (Padilla *et al.*, 2003).

Mikhailov *et al.* (2007b) have reported obtaining up to 80% regeneration from one cultivar of *P. domestica*, “Startovaya.” This was using the protocol described for transformations from leaf tissue. Even with this high rate, the subsequent transformation rates were only 2% at the highest (Mikhailov and Dolgov, 2007; Mikhailov *et al.*, 2007b).

Other reports of plum regeneration have been published both in *P. domestica* and other species. Escalettes and Dosba (1993) reported success with adventitious shoot regeneration from *P. maritima*,

P. domestica and *P. insititia* as well as a hybrid plum clone using TDZ with or without NAA with specific concentrations of hormones being clone dependent. The addition of silver nitrate enhanced regeneration possibly by blocking negative effects of ethylene. Ochatt (1992) reported regeneration of plants from protoplasts of *P. cerasifera* and *P. spinosa*. Using either a combination of NAA and Zeatin, or NAA, BAP, and Zeatin for one line of *P. spinosa* and one line of *P. cerasifera*, respectively, protoplasts were able to form microcallus from which fast-growing callus was obtained. Shoots were formed after transfer to media with NAA, BAP, and Zeatin, and then rooted and transferred to soil. A third approach to regeneration was taken by Pascual and Marin (2005) using two rootstocks, Marianna 2624 (*P. cerasifera* × *P. munsoniana*) and myrobalan 605 (*P. cerasifera*) leaf cultures. Leaf explants from *in vitro* cultured shoots were subcultured for one month with BAP and IBA then exposed to a 90-min pulse of 2,4-D before being cultured with NAA and BAP and PPM (“Plant Preservative Mixture”, Plant Cell Technology, Washington, DC) or substituting 2,4-D for the NAA. The combination of the 2,4-D pulse and the regeneration media with NAA and BAP resulted in 5–59% shoots, consistently about two- to sixfold more than controls that had no 2,4-D treatment. There were differences in which leaf explants responded to which treatment with whole leaves or basal sections yielding the highest rates. The majority of the shoots were rooted and transferred to soil with no apparent differences from the “mother” plants (Pascual and Marin, 2005).

There are two reports of regeneration with *P. salicina*, the first as part of a successful transformation (Prieto *et al.*, 2005) system modeled after Mante *et al.* (1991) with modifications of growth regulator ratios. The second group has developed the first step in a transformation system (Tian *et al.*, 2004) using a protocol based on Mante *et al.* (1991) with good success.

Several other groups have reported success with shoot regeneration of *P. domestica*, but not yet rooting. Bassi and Cossio (1991) were able to obtain high levels of shoots from leaf tissue but these shoots were not able to be rooted. Nowak and Miczynski (2002) also reported shoots from leaves using TDZ and 2,4-D as growth regulators, but rooting was not the goal. Lauri *et al.* (2001) and

Gentile *et al.* (2003) were able to regenerate from shoot apices of *P. domestica* and a plum hybrid (*P. insititia* × *P. domestica*) by culturing in the dark on BA and NAA through developing callus and inducing shoots by transferring to an auxin-free media in the light.

2.5 Testing of Activity, Stability, and Inheritance of Transgenes; Adverse Effects on Growth, Yield, and Quality

2.5.1 Developing transformation systems

Several groups have developed and are in the process of developing effective transformation systems (Table 5). Once the regenerated plants are obtained in these systems, it remains to determine if the gene of interest or marker gene is expressed. In the first report of plum transformation (Mante *et al.*, 1991) the activity of two genes, *NPTII* and *uidA* were measured using two different promoters for each. The nopaline synthase (NOS) promoter had higher levels of expression of *NPTII* than did the MAS promoter and the double 35S promoter had higher levels of expression of *uidA* protein than did the MAS promoter. This demonstrated that all the three promoters work in plum and that the expression can be measured at the protein level in plum. The results of Padilla *et al.* (2003) also detected GUS expression. *GFP* expression has been detected from plums transformed with a pNOV35SGFP vector where the *GFP* was under a 35S promoter though expression varied by tissue and age of tissue (Mikhailov *et al.*, 2007b). Preliminary results from *GFP* expression in the *P. salicina* system (Prieto *et al.*, 2005) and the *P. domestica* (Yancheva *et al.*, 2002) have not been presented.

2.5.2 PPV resistance

2.5.2.1 Pathogen-mediated resistance

To incorporate resistance to PPV, the idea of pathogen-mediated resistance was tested. The initial hypothesis was that expression of a gene encoding a viral protein would prevent that virus from replicating and hence provide resistance (Beachy *et al.*, 1990).

^(a)Selection was Kan (kanamycin), Man (mannose) from the phosphomannose isomerase gene, and Hygro (hygromycin)

^(b)Promoter/terminator for selection was 35S from cauliflower mosaic virus, MAS from mannopine synthase, NOS from nopaline synthase, CMPS from cestrium yellow leaf curling virus

^(c)Marker gene was uidA for β -glucuronidase (GUS)

^(d)GFP, green fluorescent protein; PPV-CP, papaya ringspot virus coat protein; PPV-CP, plum pox virus coat protein; PDV, prune dwarf virus; PNRSV, *Prunus* necrotic ringspot virus; TomRSV, tomato ringspot virus; anti-ACO, antisense ACC oxidase

^(e)Additions are 5' sequences added to the gene of interest. OCS/MAS-AE is trimer OCS/MAS activating elements, 5'39bCMV-CP is the 5' untranslated region to the 1st 39 bases of the coat protein of cauliflower mosaic virus, and TMV-leader is the leader sequence for tobacco mosaic virus

2.5.2.2 *PRV transgene*

Initially, the construct used to transform papaya for resistance to papaya ringspot virus (PRV), (Fitch *et al.*, 1992), was used to transform *P. domestica* (Scorza *et al.*, 1991, 1995). The idea was that the similarity between the two potyviruses, PPV and PRV, would provide “cross-protection.” The PRV coat protein gene had a 35S promoter from CaMV, the 5′ untranslated region, translation initiation codon and the first 39 nucleotides of the CaMV coat protein gene upstream of the *PRV-CP* gene followed by the 35S polyadenylation terminator sequence. The selection gene was *NPTII* with a NOS promoter (Beven *et al.*, 1983; An, 1986) and NOS terminator. The marker gene was the *uidA* gene from *E. coli*, encoding for β -glucuronidase or GUS under a 35S promoter and NOS terminator from nopaline synthase from *A. tumefaciens* (Depicker *et al.*, 1982; Beven *et al.*, 1983).

Four independent lines were isolated that grew on kanamycin selection. Leaves were positive when assayed for GUS expression and DNA analyses indicated the presence of the marker genes as well as the *PRV-CP* gene. Three lines were propagated to test for resistance in a containment greenhouse (Scorza *et al.*, 1995). The plants were graft inoculated with PPV infected tissue and monitored for symptoms and by enzyme-linked immunosorbent assay (ELISA) for a period of up to 19 months. All lines eventually had positive ELISAs and symptoms. In a study where branches were examined above or below the graft inoculation, it appeared that one line had detectable virus by real time-polymerase chain reaction (RT-PCR) only in branches that were above the inoculation point and no detectable virus after 19 months below that graft point but did have detectable virus by 32 months (Scorza *et al.*, 1995). The overall conclusion was that at least in the three lines tested, the *PRV-CP* was not able to provide a mechanism for long-term resistance to PPV.

2.5.2.3 *PPV-CP transgene*

Ravelonandro used the coding sequence of the coat protein from PPV as the pathogen gene (Ravelonandro *et al.*, 1992). The leader sequence

from the tobacco mosaic virus (TMV) coat protein and an ATG start codon was placed in frame to the coding sequence of the *PPV-CP* gene and placed this between a 35S promoter sequence and a NOS terminator sequence. It was then inserted into the same backbone sequence as the PRV construct between the selection gene *NPTII* and the marker gene, *uidA* (Scorza *et al.*, 1994). Damiano *et al.* (2005, 2007) have repeated the transformation of *P. domestica* with the same construct and Mikhailov *et al.* (2007a) have made a construct with the coat protein gene driven by a double 35S promoter.

Jacquet *et al.* (1998a) designed the *PPV-CP* gene to minimize the potential for heteroencapsidation in transgenic plants by deleting the DAG amino acid triplet that is required for aphid transmission, and by deleting the first 420 bases of the coat protein gene. The two genes were then cloned into the pGA482GG plasmid between the 35S promoter and in front of the NOS terminator sequence resembling the above construct except for the manipulated coat protein gene (Jacquet *et al.*, 1998a, b; Ravelonandro *et al.*, 2000).

Transformation with the *PPV-CP* construct pGA482GG/PPV-CP-33 generated 22 independent lines of *P. domestica*, which tested positive for GUS activity, kanamycin resistance, and were PCR positive for *PPV-CP* (Scorza *et al.*, 1994). Five of the lines were further assayed for the integration of the transgenes, the level of *CP*-mRNA (messenger RNA) and presence of *CP*-protein. All five lines had stably integrated transgenes ranging from an apparent one copy to three or more copies in C5. One line, C6 had a deletion of the *uidA* gene. The levels of *CP*-mRNA ranged from undetectable in C6 to low in C5 and very high in C4. The levels of *CP*-protein were correlated to the level of detectable mRNA with none found in C6 and C5 and the most found in C4 (Scorza *et al.*, 1994).

After proliferation, the five lines from the initial transformations were bud grafted onto rootstocks in order to test for resistance to PPV. These plants were aphid inoculated with PPV strain D (Ravelonandro *et al.*, 1997) and graft inoculated with PPV strain M (Ravelonandro *et al.*, 1997; Scorza *et al.*, 2001). These plants were followed for three or four years in the greenhouse with several cold-induced-dormancy periods. In the aphid inoculated plants, by 3 weeks 8/8 of the C5 transgenic plants were immunoblot negative for

PPV-HC or helper component protein while 51 out of 57 of the control and other transgenic lines were positive. By three years, all of the 57 control and non-C5 transgenic lines were positive with most showing symptoms while none of the C5 lines were positive or exhibited symptoms.

Similar results were obtained in the two experiments that were inoculated by grafting on infected budwood. The C5 line never had detectable symptoms, nor did it have positive immunoblots or ELISAs during the three or four years while all the other lines at one time or another had symptoms, positive immunoblots and positive ELISAs. In one set of experiments, C5 did, however have virus detectable by IC-RT-PCR and uninfected buds grafted on the infected C5 lines did show virus symptoms within several months (Scorza *et al.*, 2001). In the other set of experiments, no virus could be detected in C5 using IC-RT-PCR and uninfected buds grafted onto C5 remained virus free (Ravelonandro *et al.*, 1997).

It was determined that the mechanism for the resistance of the C5 line was due to post-translational gene silencing (PTGS) (Scorza *et al.*, 2001; Hily *et al.*, 2005). In comparison to the other transgenic lines, C5 had high rates of transcription of the *CP*-transgene, very low levels of mRNA accumulation, specific methylation of the *CP*-transgene and very low levels of virus upon graft inoculation (Scorza *et al.*, 2001). It was postulated that the complex arrangement of the insertion of transgenes, specifically the arrangement of the coat protein gene, induced the silencing mechanism to trigger the destruction of sequences related to the *CP* such as the infecting PPV. In looking for small interfering RNAs (siRNAs), one of the hallmarks of silencing, two size classes of siRNAs were detected in uninfected C5 and neither was detected in another multicopy transgenic line, C3 nor in controls (Hily *et al.*, 2005). In infected lines the smaller class of siRNAs was detected in all while only the larger class was detected in the resistant C5 suggesting that that larger class of siRNAs was responsible for the resistance of C5.

One of the major questions was would this PTGS mechanism of resistance to PPV work in the field. Hily *et al.* (2004) analyzed the level of resistance in a field planting in Poland of C5 trees and other transgenic lines and control trees under both natural infection by aphids and by chip-bud inoculation. After four years, none of

the uninoculated C5 trees had become infected with PPV while 37 out of 39 other trees were infected, mostly in the first season. As was seen in one greenhouse experiment (Scorza *et al.*, 2001), when the C5 trees were inoculated through chip budding, PPV could be detected in a few leaves by IC-RT-PCR and by ELISAs. Symptoms were evident only in a few leaves after one year and those disappeared by four years. C5 in the field had high levels of specific methylation of the coat protein transgene relative to other transgenes and relative to other transgenic lines such as C3. C5 also had only low levels of detectable *CP*-mRNA, similar to the levels seen in the greenhouse studies (Scorza *et al.*, 1994). Results from field trials in Poland (8 years) and Spain (7 years) were similar in that no PPV was found in uninoculated C5 trees, while the majority of the other trees in the plantings were infected (Malinowski *et al.*, 2006). In the chip-bud-inoculated lines in Poland, all trees except C5 had detectable PPV by symptoms by the first year. C5 exhibited symptoms on less than five leaves per tree in year 2 and in the following years. Only in C5 was the detection of PPV by ELISA or IC-RT-PCR limited to those leaves that exhibited symptoms (Malinowski *et al.*, 2006). Overall, the field trials demonstrated that C5 was highly resistant to natural infection through aphids and was significantly resistant when chip-bud inoculated.

To determine if the resistance could be transferred, hybridizations were made with C5 (Ravelonandro *et al.*, 1998; Scorza *et al.*, 1998). C5 pollen was used to hybridize with a *P. spinosa* rootstock (apparently tetraploid) (Ravelonandro *et al.*, 1998) with the goal of transferring the PPV resistance to rootstocks. GUS expression determined that about half of the progeny (44/97) had received a transgene from C5 and PCR was used to confirm that those progeny had also received the *CP*-transgene from C5. After two cycles of growth and cold-induced dormancy (CID), the hybrid seedlings that had been chip-bud inoculated with PPV were symptomless, ELISA negative and negative on immunoblots indicating that they were resistant to PPV like the C5 controls (Ravelonandro *et al.*, 2001).

The *PRV-CP* transgenic lines were hybridized with C5 as well as selfed, yielding seedlings that contained only the *PPV-CP* insert, or only the *PRV-CP* insert, or both inserts or neither (Scorza

et al., 1998). These were graft inoculated with PPV and monitored. After eleven months following inoculation, only those seedlings that contained the *PPV-CP* had no symptoms and were 100% ELISA negative. All the rest of the plants had detectable symptoms. The pattern of multiple fragments that hybridized to the *PPV-CP* probe, seen in DNA blot analyses of C5 was seen in all the resistant seedlings, supporting the fact that the complex pattern of transgene insertion in C5 segregates as a single-linked loci with the resistance phenotype.

Based on earlier results that the resistance could be easily transferred, Ravelonandro *et al.* (2002) moved that resistance into hybrids with commercial *P. domestica* cultivars. Seedlings were screened for GUS expression and those that tested positive (56:59 and 16:24) were further analyzed using PCR assays to determine if the *PPV-CP* were present and to confirm the presence of the *uidA* gene. A number of the plants that contained the transgene *PPV-CP* as well as nontransgenic controls were replicated and then inoculated by either grafting on to an infected microrootstock or by chip budding. Infection was monitored by immunoblots or by IC-RT-PCR. All of the *PPV-CP* carrying seedlings were negative for virus through two cycles of growth and CID (Ravelonandro *et al.*, 2002), again confirming the transfer of the resistance as a single Mendelian gene.

The transfer and linkage of the multiple transgenes in C5 was confirmed in field studies over a number of years by looking at the genotypes of open pollinated C5 fruit in which there was an 1:1 segregation of GUS activity to no activity (118:100 and 120:92), and in 50 DNA blot analyses of GUS positive progeny, 49 had the expected pattern of *CP* fragments. The 50th had a more complex pattern suggesting hybridization with a nearby *PPV-CP* transgenic line other than C5 (APHIS, 2006, petition for deregulation).

Molecular characterization of the resistant progeny supported the inheritance of the PTGS mechanism of resistance (Scorza *et al.*, 2001; Hily *et al.*, 2004). Resistant seedlings had highly methylated *CP*-transgene DNA. They also had the two size classes of siRNA and low levels of *CP*-mRNA. This was apparent from an early stage of germination (2 weeks) as well as in ungerminated embryos (Hily *et al.*, 2004).

C5 has been patented as “HoneySweet” (Scorza *et al.*, 2004), and in all the testings, propagating sexual and asexual, and in grafting on many different types of rootstock, no unusual phenotypes have been detected. C5 is an upright tree form with vigorous growth, good productivity and yields high fruit quality with an average brix of 21.5°, medium- to large-sized fruit with blue skin and yellow flesh. A complete description of the tree and fruit are in the plant patent (Scorza *et al.*, 2004).

2.5.2.4 *PPV hairpin transgenes*

Based on the mechanism of PTGS to obtain the resistance in the C5 as well as many other reports in the literature, constructs were made that formed hairpin or double stranded RNAs from several of the *PPV* genes. The majority of these have been tested in tobacco but the constructs are ready for *Prunus* systems using not only a 35S promoter but a *rolC* promoter from *Agrobacterium rhizogenes* (Schmulling *et al.*, 1989; Pandolfini *et al.*, 2003; Di Nicola-Negri *et al.*, 2005). Hily *et al.* (2007) have taken a similar approach using both a short- and a full-length fragment of the *PPV-CP* gene as well as having them driven by a 35S promoter or a peach chlorophyll A/B binding protein minimal promoter. The hairpin constructs of the *PPV-CP* were placed in a pHellsgate 8 vector (Wesley *et al.*, 2001) with the sense and antisense orientations separated by a pyruvate orthophosphate dikinase intron and terminated with an octopine synthase terminating sequence. The selective gene was *NPTII*. After testing in *Nicotiana benthamiana*, *P. domestica* were transformed with the most effective construct that carried the full-length *CP* under the 35S promoter (Hily *et al.*, 2007).

Using knowledge from the studies that demonstrated that C5 resistance was based on a PTGS-silencing mechanism, many groups designed constructs that enhanced the generation of a PTGS response to obtain resistance to PPV. This was well demonstrated in tobacco using various *PPV* genes and several promoters (Pandolfini *et al.*, 2003; Di Nicola-Negri *et al.*, 2005; Hily *et al.*, 2007). In these studies, a large number of the transformants exhibited PTGS, 5/5 with the *rolC* promoter-*PPV-CP* (Pandolfini *et al.*, 2003), 41/41 with the 35S promoter and various pieces of the *PPV P1*,

HC-Pro and *P3* genes (Di Nicola-Negri *et al.*, 2005), and 37/48 using different lengths of the *PPV-CP* and the 35S and a Chlorophyll A/B binding protein promoter (Hily *et al.*, 2007). Only Hily *et al.* (2007) have introduced the hairpin construct into plum yielding lines that produce siRNAs. One line contained the 35S promoter and the full-length *CP* sequence and produced siRNAs in similar amounts to that of C5 and of the same two size classes seen in C5. The *CP*-transgene was highly methylated, which is consistent with the PTGS phenotype. Inoculation by aphids resulted in no detectable virus in the transgenic line tested while the susceptible controls were all positive. These results suggest that the hairpin constructs are an efficient way to generate resistance to PPV.

2.5.2.5 Other PPV resistance lines

A number of laboratories have reported transformation of plum with genes that could confer PPV resistance (da Camara Machado *et al.*, 1999; Damiano *et al.*, 2005, 2007; Ilardi *et al.*, 2007; Mikhailov *et al.*, 2007a). The results of resistance testing have not been reported.

2.5.3 Regulation of ethylene and effects on ripening

The complete cDNA (complementary DNA) sequence of *ACC Oxidase 1* gene from peach (Callahan *et al.*, 1992) was PCR amplified and digested with *EcoRI*, gel purified and ligated into an *EcoRI* digested pGA482GGI vector. The vector was constructed from the pGA482GG (Fitch *et al.*, 1992) vector by inserting a *uidA* gene with an intron (S. Gelvin, personal communication). The *uidA* was driven by MAS promoter and a 35S promoter and terminated by an octopine synthase terminator (pCNLS6). A 35S promoter and NOS terminator with a multiple cloning site in between was inserted between the NPTII selectable marker and the *uidA* marker. The antisense ACO *EcoRI* fragment was cloned into this multiple cloning site (Padilla *et al.*, 2003; Bill Farmire, personal communication).

Callahan and Scorza (2007) used *P. domestica* to investigate the effects of down-regulating ethylene

on the ripening characteristics. Fifteen antisense *ACO* lines were analyzed for the amount of ethylene evolved during ripening as well as the time of ripening and the brix of the fruit as it ripened. Results after three years of fruiting suggested that the antisense fruits were slower to ripen, had lower levels of ethylene, and had slightly lower levels of brix in comparison to 14 lines of nontransgenic seedling controls. This suggested that the antisense *ACO* gene was down-regulating the amount of ethylene produced, which was correlated with slower softening and a lower brix. Molecular studies to confirm the phenotyping are in progress.

2.6 Specific Regulatory Measures Adopted

All PPV experiments were performed with the required permits. As PPV is a foreign pest in the United States, all inoculation studies were done in a P3 quarantine greenhouse at Fort Detrick, MD. PPV was classified as a select agent and stricter controls as well as security measures were undertaken that restricted the possession of genes in addition to the virus. Again, work was done strictly in Fort Detrick by fully approved personnel.

APHIS field permits as well as greenhouse permits were obtained for all transgenic work in the United States. The field permits initially called for all transgenic propagatable material to be collected and burned including prunings. The trees were contained prior to and throughout bloom time so no release of pollen was possible. Since *P. domestica* is a hexaploid and not compatible with most *Prunus* species, when it was necessary to analyze fruit, restrictions were modified to allow open pollination as long as there were no cross-compatible trees in the area. All fruit and seed as well as clippings had to be collected and destroyed.

In order to further test and potentially release the PPV-resistant transgenic cultivar “HoneySweet” (C5) in the United States, it must be approved by three different federal agencies. “USDA-APHIS has jurisdiction over the planting of genetically engineered plants. EPA has jurisdiction over planting and food and feed uses of pesticides engineered into plants. These

3. FUTURE ROAD MAP

3.1 Expected Products

The majority of programs using transgenic plums are working to generate PPV resistance (Table 7), so the first predicted commercial product of transgenic breeding could be a PPV-resistant plum. It could come from the release of C5-“HoneySweet” directly or it may come from a cultivar resulting from breeding with “HoneySweet” to introduce the resistance into a plum type of choice (Ravelonandro *et al.*, 1998, 2002; Scorza *et al.*, 1998). In the United States, if “HoneySweet” is deregulated, the progeny of “HoneySweet” will automatically be deregulated in regard to the transgenes from “HoneySweet.” This would mean that the fastest PPV-resistant plums would come from hybridizations with “HoneySweet.” In this manner the PTGS method of resistance could be combined with nontransgenic germplasm with different modes of resistance resulting in a cultivar with stacked resistance mechanisms.

The next generation of transgenic plums will still be for resistance to PPV as well as other viruses using the same mechanism of resistance, PTGS (Padilla *et al.*, 2003; Dolgov *et al.*, 2005; Hily *et al.*, 2005). This generation will use the knowledge from “HoneySweet” to speed up the process of finding resistant lines, for example, by the introduction of hairpin constructs to induce the PTGS system (Mikhailov *et al.*, 2007a; Hily *et al.*, in press), and utilizing genes that will make the deregulation easier, such as using genes

that have been deregulated previously. This next generation of transgenic plums for release will be produced to minimize the use of existing intellectual property where possible to maximize the potential for commercial releases.

The third generation of potential products will be improvements in traits such as fruit quality aspects, productivity and disease resistance; traits that have been successfully approached through conventional breeding but will be better targeted or with a novel phenotype not easily obtained through conventional breeding (Prieto *et al.*, 2005; Callahan and Scorza, 2007). The identification of these improved traits will come through better knowledge of the molecular biology and physiology of those traits, as well as knowledge gained from genome sequencing of both peach and apple by the Joint Genome Institute and the Istituto Agrario San Michele all’Adige, respectively.

3.2 Addressing Risks and Concerns

3.2.1 Environmental challenges

APHIS considers eight potential environmental impacts for C5 plum including: (1) potential impacts from gene introgression, (2) potential impacts based on relative weediness, (3) potential impact on nontarget organisms, (4) potential impacts on biodiversity, (5) potential for viral interactions, (6) potential impacts on commercial use, (7) potential impacts on organic

Table 7 Status of transformed plum

Trait of interest	Group	Location	Gene of interest	Greenhouse results	Field trials	Releases	Reference
PPV resistance	Scorza/Ravelonandro	USA	PPV-CP	PPV resistance	Yes	Deregulation	Scorza <i>et al.</i> , 1994
PPV resistance	Scorza/Ravelonandro	USA	PRSV-CP	No long-term PPV resist	Yes		Scorza <i>et al.</i> , 1995
PPV resistance	Ravelonandro/Scorza	France	PPV-CP-DAG/RC	PPV recovery			Ravelonandro <i>et al.</i> , 2000
PPV resistance	Scorza/Ravelonandro	USA	PPV-CP-hairpin RNAi	PPV resistance			Hily <i>et al.</i> , 2005, 2007
Delayed softening	Callahan/Scorza	USA	peach-anti-ACO	Wound-induced ethylene	Yes		Callahan and Scorza, 2007
PPV resistance	Tian/Brown	Canada	PPV-P1/RNAi				Personal communication
PPV resistance	Mikhailov/Dolgov	Russia	PPV-CP/pmi/RNAi				Mikhailov <i>et al.</i> , 2007a
PPV resistance	Damiano	Italy	PPV-CP	PPV resistance			Damiano <i>et al.</i> , 2005, 2007

farming, and (8) potential impacts on raw or processed agricultural commodities (APHIS, 2006, environmental assessment). A number of these points have been addressed. *P. domestica* is hexaploid suggesting that its ability to outcross to wild relative is very low, since there are few wild hexaploid *Prunus* species. If it did outcross, the effect of the incorporation of C5 transgenes for kanamycin resistance, PPV resistance and *uidA* on wild relatives does not appear to confer any kind of advantage except to be resistant to PPV. On the point of weediness, C5 has a normal upright plum growth habit, hence there should be no impact on increased weediness. The impact on nontarget organisms was addressed in the petition for nonregulatory status (<http://www.aphis.usda.gov/brs/aphisdocs/04.26401p.pdf>), with a study on insects found on C5 plants. No differences were seen between transgenic and nontransgenic trees. In addition, NPTII and GUS proteins that C5 could produce (C5 has no detectable PPV coat protein), have been “classified as exempt from the requirement of a tolerance in or on all raw agricultural commodities when used as plant-pesticide inert ingredients” (59 Federal Register 49353, September 28, 1994 and 66 Federal Register 42957–42962, August 16, 2001 for NPTII and GUS, respectively). Biodiversity issues are a factor of the weediness or advantage/disadvantage conferred by the transgenes in C5 and as there appear to be none, there should be no effect on biodiversity.

The case for viral interactions with a consequent development of new viruses has been investigated. Virus interactions can have three major results. The first is that a viral genome may be “packaged” by a coat protein made by the transgenic tree that allows the “new” virus to be transmitted by aphids to a new host or heterologous encapsidation (Lecoq *et al.*, 1993; Tepfer, 2002). A study to prevent any transencapsidation of the transgene was done by Jacquet *et al.* (1998a, b). Constructs were made of the *PPV-CP* gene with either a deletion of the DAG, amino acid triplet responsible for aphid transmission, or a deletion of the start codon. These were tested in tobacco with good success both in generating resistance and in preventing transmission. The constructs were transferred to plum and are still in the process of being evaluated (Ravelonandro *et al.*, 2000). “HoneySweet” makes no detectable coat protein

(Scorza *et al.*, 1994), hence none is available for the potential encapsidation.

The second potential risk with virus interaction is for recombination between viral genomes. Since the mechanism of resistance in “HoneySweet” is PTGS, there are very low levels of RNA in the cytoplasm and similar RNAs are targeting for degradation (Scorza *et al.*, 2001), so presumably any recombinant virus would also be targeted for degradation. The risk of a synergy effect that would enhance the infection of another virus in the presence of the transgene was addressed when Ravelonandro *et al.* (2007) co-infected “HoneySweet” and controls with several different viruses mixed with PPV, including apple chlorotic leaf spot virus (ACLSV), prune dwarf virus (PDV), and *Prunus* necrotic ringspot virus (PNRSV). None of these viruses affected the “HoneySweet” response and resistance to PPV.

Approaches to minimize the spread of transgenes have been developed but have yet to be tested in plum. One approach to prevent the dissemination of transgenes through sexual material is to excise the transgene in pollen and fruit (Mlynárová *et al.*, 2006) or by restricting the transgenes to chloroplasts (Daniell, 2002). Transmission of transgenes to associated microorganisms is another possible mechanism for the release of transgenes. As of yet, no transmission has been documented (Kay *et al.*, 2002; Nielsen and Townsend, 2004).

3.2.2 Human health challenges

The worries about affects of transgenic food are the effect of foreign genes on human health as well as the transmission of genes to microflora in the human gut. The transgenic product consumed will be the fruit for transgenic plums. “HoneySweet” has had fruit analyzed (Scorza *et al.*, 2005, 2007; APHIS, 2006, petition) with no parameters outside the normal range of other nontransgenic plum cultivars. A study has also been done for FDA approval on predicting any new potentially antigenic proteins in C5, again with negative results. The potential new products of “HoneySweet”, NPTII protein and *uidA* protein, do not appear to be a problem (Gilissen *et al.*, 1998; Kuiper *et al.*, 2001). The potential for transfer of those genes to intestinal

organisms is under research from other groups as the marker genes as well as others are in a very large number of transgenic crops already released (Netherwood *et al.*, 2004). A recent European Food Safety Authority statement (<http://www.efsa.europa.eu/en/science/gmo/statements0/npt2.html>), concluded that the likelihood of transferring the *NPTII* gene from plants into the human gut was very low and the possible transfer than into a bacterium was very low with resulting stable incorporation and expression being a very low probability. This low probability accounts for the transfer and expression not being seen under natural conditions. They further conclude that the *NPTII* gene poses neither any risk to human health nor to the environment.

3.3 Expected Technologies

The most desired technology would be a reliable transformation system that is not cultivar specific. This will come as new groups are developing transgenic plum lines and more information is gained about plant hormone ratios in plum (Table 7). Along with a reliable transformation system should come improved selection schemes, like mannose or hygromycin (Dolgov *et al.*, 2005; Mikhailov *et al.*, 2007a) and novel promoters to help regulate the genes of interest and to possibly minimize expression of transgenes in edible parts. With the base knowledge from genomics and expression systems such as microarrays, genes can be identified that will have expression in desired tissues and developmental stages as well as in response to various stimuli. Appropriate promoter sequences can be selected from these. Systems that have been developed in other plants will be transferred to plum, such as systems that excise marker genes or marker-free transformation techniques (Yoder and Goldsbrough, 1994; Ow, 2002; Zhang *et al.*, 2003; Goldstein *et al.*, 2005; López-Noguera *et al.*, 2007). This is all expected technologies as they work in other plant systems and with time will be modified to work with plum.

As with the transformation systems being applied to plum, other current molecular tools are being applied to *Prunus* and can then be utilized for plum in order to identify traits of interest for manipulation and what processes those

traits interact with. There are continuing studies on deducing the *Prunus* genome (<http://www.bioinfo.wsu.edu/gdr>). Data from molecular mapping studies in various *Prunus* crops are being applied to a consensus map (Dirlewanger *et al.*, 2004b) as well as The Rosaceae Consortium of Mapping Populations (RosPOP) (<http://www.mainlab.clemson.edu/gdr/community/international/rospop.shtml>) for quantitative trait loci (QTL) and mapping resources. There will be more microarrays available (ESTree Consortium, 2005) to use to determine RNA expression patterns. With these expected technologies, more complex traits can be analyzed and may find themselves amenable to transgenic breeding.

3.4 Specific Details for Intellectual Property Rights (IPR), Public Perceptions, Industrial Perspectives, Political, and Economic Consequences

IPR issues as well as public acceptance, Industry support and acceptance and the resulting political and economic consequences are important issues to address in the commercial production of transgenic crops. Obviously, these issues have been dealt with in the releases and uses of corn and soybeans with various novel genes for herbicide resistance or insect resistance. The potential commercial releases of transgenic plums are many years behind as are the specific details. At present time, there are no commercial releases of transgenic plums. Only “HoneySweet”, the PPV-resistant transgenic plum has even been patented (Scorza *et al.*, 2004). Future releases will follow the established approval processes by APHIS, EPA, and FDA, and then the specific details for IPR and acceptance can be approached and in general will be no different than for those crops commercially developed prior to plums.

1. INTRODUCTION

1.1 History, Origin, and Distribution

1.1.1 Blueberry and cranberry

Several species of *Vaccinium* are important commercially. Most production comes from species of section *Cyanococcus* including cultivars of *Vaccinium corymbosum* L. (highbush blueberry) and *Vaccinium ashei* (rabbiteye blueberry), and native stands of *Vaccinium angustifolium* (lowbush blueberry). Highbush cultivars are further separated into northern or southern types depending on their chilling requirements and winter hardiness. *Vaccinium macrocarpon* (large cranberry), a member of section *Oxycoccus*, is also an important domesticated species. *Vaccinium myrtillus* (bilberry, whortleberry) in section *Myrtillus* and *Vaccinium vitis-idaea* (lingonberry) in section *Vitis-idaea* are collected primarily from the wild.

All of the wild, edible *Vaccinium* species have been harvested for thousands of years by indigenous peoples. There are suggestions that the Indians of eastern North America intentionally burned native stands of lowbush blueberries to renew their vigor. The cultivation of *Vaccinium* by immigrant Europeans first began in the early 19th century when cranberry farmers in the Cape Cod area of Massachusetts started building dykes and ditches to control the water levels in native stands. Highbush and rabbiteye blueberries were first domesticated at the end of the 19th century. Plants

were initially dug from the wild and transplanted into New England and Florida fields.

Most of the commercial production of blueberry now comes from highbush and lowbush types, although rabbiteyes are important in the North American southeast and hybrids of highbush × lowbush (half-highs) have made a minor impact in the upper midwest of the United States. There is also growing interest in growing rabbiteye cultivars in the Pacific Northwest and Chile. Highbush blueberries are grown in 36 states in the United States, in six Canadian provinces, and in Australia, Chile, Argentina, New Zealand, and a number of countries in Europe. The largest acreages are in Michigan, New Jersey, North Carolina, Oregon, and Washington in the United States, and British Columbia in Canada. There are strong signs that an important highbush industry will be established in California. Commercial production of lowbush blueberries is restricted to Maine, Quebec, and Nova Scotia. Cranberries are grown primarily in Wisconsin, Massachusetts, New Jersey, Washington, and Oregon, with limited plantings in British Columbia, Michigan, Nova Scotia, and Quebec.

1.1.2 Cane fruit

The European red raspberry, *Rubus idaeus* subsp. *vulgaris* was first mentioned in the historical record by Pliny the Elder. He described it as “ida” fruit grown by the people of Troy at the base of

Mount Ida. However, it is likely that these plants originally came from the Ide Mountains of Turkey, as raspberries were not native to Greece (Jennings, 1988). Raspberries gradually grew in popularity over the centuries and by the 1500s, *R. idaeus* subsp. *vulgaris* was cultivated all over Europe. The North American subsp. *strigosus* was introduced into Europe in the early 19th century and natural hybrids with subsp. *vulgaris*, resulted in much advancement. In fact, most red raspberry cultivars dating from this period are hybrids of these two species (Daubeney, 1983; Dale *et al.*, 1993).

The black raspberry of North America, *Rubus occidentalis*, was not cultivated until the 19th century, probably because of its abundance in the wild and difficulties with its propagation (Jennings, 1988). It does not sucker like red raspberries and growers had to learn to propagate it by bending over the stem tips. Most early cultivars of black raspberry were wild selections, and in fact, purple raspberry hybrids of black and red raspberry may have been the first raspberry cultivars that contained black raspberry genes.

The most important European blackberry, *Rubus laciniatus* Willd., was probably domesticated in the late 17th century in England and was imported to the Northwestern coast of North America before 1860 (Jennings, 1988). *R. laciniatus* quickly became feral in the western United States and the widely grown "Thornless Evergreen" was selected from the wild in the early 1930s.

The earliest cultivars of eastern North American blackberries were selected in the 1800s, as forests were actively cleared and numerous wild species spread and hybridized. Three natural hybrids of *Rubus allegheniensis* × *Rubus frondosus*, "Lawton", "Dorchester", and "Texas Early" (Crandell), played a particularly key role in the domestication of the crop, although early cultivars were also selected from pure *R. allegheniensis* ("Snyder"), *Rubus argutus* ("Early Harvest"), and *Rubus ursinus* ("Aughinbaugh"), and interspecies crosses of *R. allegheniensis* × *R. argutus* ("Eldorado"), and *Rubus baileyanus* × *R. argutus* ("Lucretia" and "Austin Mayes").

1.1.3 Strawberries

Fragaria vesca, the alpine strawberry or fraise de bois, was the first strawberry domesticated. It was

originally brought into gardens by the ancient Romans and Greeks, and by the 1300s, was being grown all across Europe (Darrow, 1966). *F. vesca* had its widest popularity in the 1500s and 1600s in Europe before the introduction of strawberry species from the New World. The musky flavored *Fragaria moschata* (Hautbois or Hautboy) was also planted in gardens by the late 15th century, along with the green strawberry, *Fragaria viridis*. *F. viridis* was used solely as an ornamental all across Europe, while *F. moschata* was utilized for its fruit by the English, Germans, and Russians.

F. vesca dominated strawberry cultivation in Europe, until *Fragaria virginiana* from eastern Canada and Virginia began to replace it in the 1600s. All of the clones that arrived in Europe were wild in origin, as the aboriginal peoples of North America did little gardening with strawberries. A Chilean clone of *Fragaria chiloensis* found its way into Europe in the 1700s compliments of a French spy, Captain Amédée Frézier (Darrow, 1966; Wilhelm and Sagen, 1974). It was domesticated 1000 years ago by the indigenous Mapuches and was spread widely by the Spanish during the colonization period. Unfortunately, early reports on the Chilean strawberry were negative, as the plants were largely barren because Frézier had inadvertently brought back staminate plants. French horticulturalists solved the problem when they discovered that the "Chili" would produce fruit when pollinated by *F. moschata* or *F. virginiana*. The Chilean strawberry reached its highest acclaim in Brittany, and by the mid-1800s, there was probably more *F. chiloensis* cultivated in France than its native land.

Unusual seedlings began to appear in Brittany and other gardens with unique combinations of fruit and morphological characteristics. While the origin of these seedlings was initially clouded, the great French Botanist Antoine Nicholas Duchesne determined in 1766 that they were hybrids of *F. chiloensis* × *F. virginiana* and he named them *Fragaria* × *ananassa* to denote the perfume of the fruit that smelled like pineapple (*Ananas*). It is not clear where the first hybrids of the Pineapple or Pine strawberry appeared, but they must have arisen early in the commercial fields of Brittany, and in botanical gardens all across Europe.

Formal strawberry breeding was initiated in England in 1817 by Thomas A. Knight. He was

one of the first systematic breeders of any crop, and used clones of both *F. virginiana* and *F. chiloensis* in his crosses. Thomas Laxton of England was the most active breeder during the later part of the 18th century and released a number of important cultivars including “Noble” and “Royal Sovereign”. Charles Hovey, of Cambridge, Massachusetts, produced the first important North American cultivar, “Hovey.” It was the first cultivar of any fruit to come from an artificial cross in America and for a while made the strawberry the major pomological product in the country (Hedrick, 1925).

The dessert strawberry, *F. × ananassa*, now dominates strawberry cultivation and is grown in all arable regions of the world. *F. vesca* is generally restricted to home gardens where its small, aromatic fruits are considered a delicacy; most of the cultivars grown are everbearers. *F. chiloensis* is currently grown to a small extent in Chile, but has been largely replaced by *F. × ananassa*. Neither *F. viridis* nor *F. moschata* is of any current commercial importance.

Most of the strawberries of *F. × ananassa* grown across the world are bred to fruit under short-day conditions, although day-neutral types dominate in California and other Mediterranean climates (Hancock, 1999). Two major production systems are utilized in the world—hills and matted rows. The matted row system employs runners as the primary yield component. Both mother and daughter plants are allowed to runner freely, with periodic training into narrow rows. The hill or “plasticulture system” relies on crowns as the primary yield component, and any runners that form are removed. The hill system is used primarily in areas having warm winters and either hot or moderate summers such as California, Florida, Italy, and Spain. Matted rows are used to grow short-day cultivars in climates with short summers and cold winters, such as continental Europe and northern North America.

1.2 Botanical Description

1.2.1 Blueberry and cranberry

The genus *Vaccinium* is very widespread, with high densities of species being found in the Himalayas,

New Guinea, and the Andean region of South America. The origin of the group is thought to be South American. Estimates of species numbers vary from 150 to 450 in 30 sections (Luby *et al.*, 1991). The taxonomy of the commercially important sections *Cyanococcus*, *Oxycoccus*, *Vitis-idea*, and *Myrtillus* (Table 1) has been difficult to resolve due to complex polyploidy series ($x = 12$) and a general lack of chromosome differentiation and crossing barriers within sections. The primary mode of speciation has been through unreduced gametes.

All the polyploid *Cyanococcus* are likely to be of multiple origins and active introgression between species is ongoing. Most homoploids freely hybridize and interploid crosses are frequently successful, through unreduced gametes. The tetraploid highbush blueberry *V. corymbosum* has been shown to be an autopolyploid (Krebs and Hancock, 1989). Vander Kloet (1980) found the variation pattern in highbush and rabbiteye to be so complex that he placed all crown forming section taxa ($2x$, $4x$, and $6x$) under the name *V. corymbosum*. Most horticulturalists still distinguish the hexaploid *V. ashei* from tetraploid *V. corymbosum*, and continue to recognize at least one distinct diploid, *Vaccinium elliottii* (Luby *et al.*, 1991). The lowbush blueberry, *V. angustifolium* appears to be a direct descendant of *Vaccinium pallidum × Vaccinium boreale*, but introgression with *V. corymbosum* may have also influenced its subsequent development (Vander Kloet, 1977).

V. macrocarpon is an endemic of eastern North America and is thought to be the most primitive species in section *Oxycoccus* (Camp, 1945). Its closest relatives are diploid, tetraploid, and hexaploid races of *Vaccinium oxycoccus* that have circumboreal distribution. Gene exchange is now severely limited between the species due to a disjunct distribution and a flowering date difference of 3 weeks (Vander Kloet, 1988). *V. myrtillus* is very similar to *Vaccinium scoparium* and may have been derived in the Rocky Mountains of North America (Camp, 1945). There has been little speculation about the origin of *V. vitis-idea*, but it must be closely related to *V. myrtillus*, since hybrids have been discovered between these two species at numerous locations across northern Europe (Luby *et al.*, 1991).

1.2.2 Cane fruit

Raspberries and blackberries are in the genus *Rubus* of the Rosaceae. There are 12 subgenera recognized within *Rubus*, with the domesticated raspberries being found in the *Eubatus* and *Cylactis* (Table 2), while the domesticated blackberries are found in *Idaeobatus*, *Caesii*, *Suberecti*, and *Corylifolii* (Table 3). *Eubatus* are found in two geographically distinct sections, the *Moriferi* (Europe and Asia) and *Ursini* (western North America). *Cylactis* has an arctic and subarctic distribution. The *Corylifolii* species are located in eastern North America, being mostly concentrated in the southern United States. The *Caesii* contains only one species, *Rubus caesii*, which is found in Europe and Asia. Species of the *Suberecti* are located in the United Kingdom, Scandinavia, and North America. These species may be derivatives of *R. caesius* crossed with *R. idaeus*. Genomic *in situ* hybridization (GISH) and fluorescent *in situ* hybridization (FISH) have been utilized to

distinguish between raspberry and blackberry chromosomes, and identify translocations (Lim *et al.*, 1998).

The subgenus *Idaeobatus* contains about 200 wild species with nine sections. Almost all of the raspberry species in the *Idaeobatus* subgenera are diploid ($2n = 14$), with a few triploid and tetraploid types. *Idaeobatus* species are concentrated in northern Asia, but are also located in east and South Africa, Europe, and North America (Jennings, 1988). The greatest diversity is found in southwest China, which may be the center of origin of the subgenus.

The most important commercial taxa of *Idaeobatus* are: (1) the European red raspberry (*R. idaeus* ssp. *vulgatus* Arrhen.), (2) the North American red raspberry (*R. idaeus* ssp. *strigosus* Michx.), (3) the North American red raspberry (*R. strigosus* spp. *strigosus* Michx.), and (4) the black raspberry (*R. occidentalis* L.). Crosses between black and red raspberries have produced the purple raspberries (*R. neglectus* Peck). The

^(a)Source: Jennings, 1988; Daubeney, 1996

important arctic raspberries *R. arcticus* L. and *R. stellatus* Sm. are contained in *Cylactis*, which is closely related to the *Idaeobatus*. The Andean blackberry, *R. glaucus* Benth., is also classified in the *Idaeobatus*, even though its fruit adhere to the receptacle. It is likely a natural allotetraploid hybrid of a diploid black raspberry and a diploid South American blackberry, perhaps *R. bogotensis* (Jennings, 1988).

The major commercial taxa of raspberries share a considerable amount of interfertility. The red raspberries of Europe, *R. idaeus*, and the American *R. strigosa*, are completely interfertile and should probably be considered the same species. *Rubus arcticus* and *R. stellatus* are also highly interfertile and have been jointed as subspecies of *R. arcticus* (ssp. *arcticus* and ssp. *stellatus*). Hybrids between these two species are more commonly cultivated than pure species types (Jennings *et al.*, 1989). The cross of *R. idaeus* × *R. occidentalis* is only successful if *R. occidentalis* is used as the female parent, although bud pollination and heat treatment can help

overcome this unilateral incompatibility (Hellman *et al.*, 1982). At least 40 additional species in *Idaeobatus* have also been used in raspberry breeding, along with a few species in the *Cylactis*, *Anoplobatus*, *Chamaemorus*, and *Malachobatus* (Daubeney, 1996).

Blackberry cultivars generally have complex backgrounds and are often composed of species at several ploidy levels in four subgenera: *Eubatus*, *Caesii*, *Suberecti*, and *Corylifolii*. Four diverse groups of blackberries have been domesticated: (1) the European blackberries that were derived from a group of diploid and polyploidy species ($2n = 28, 42$, and 56). The background of the European cultivars is so complex that the designation *R. fruticosus* L. agg. is sometimes used (Daubeney, 1996), (2) erect blackberries and trailing dewberries domesticated from mostly diploid and tetraploid species ranging across eastern America, and (3) trailing black raspberries generated from only polyploid species from western America ($2n = 56, 84$). Blackberries and raspberries have also been hybridized to produce intersectional

hybrids such as Loganberries and tayberries ($2n = 42$), and Boysenberries and youngberries ($2n = 49$).

1.2.3 Strawberry

The strawberry belongs to genus *Fragaria* in the Rosaceae. Its closest relatives are *Duchesnea* and *Potentilla*. There are four basic fertility groups in *Fragaria* that are associated primarily with their ploidy level or chromosome number. The most common native species, *F. vesca*, has 14 chromosomes and is considered a diploid; its genome size is relatively small at 164 Mb (Akiyama *et al.*, 2001). The most important cultivated strawberry, *F. × ananassa*, is an octoploid with 56 chromosomes. It is an accidental hybrid of *F. chiloensis* and *F. virginiana* that arose in the mid-1700s when plants of *F. chiloensis* from Chile were

planted in France next to *F. virginiana* from the eastern seaboard of the United States.

An accurate taxonomy of the strawberry species is still emerging (Table 4). While the European and American species of *Fragaria* have been rigorously defined by Staudt (1959, 1989), the species situation in Asia is much more ambiguous (Hummer, 1995). There is no overall consensus of what species exist in China and published descriptions have sometimes relied on limited collections. Diploid, tetraploid, and hexaploid species are found in Europe and Asia, but octoploids are restricted to the New World and perhaps the Iturup Island northeast of Japan (Staudt, 1989). Only one diploid species, *F. vesca*, is located in North America. The genomic complement of the octoploids is likely AAA'A'BBB'B' (Bringhurst, 1990), with *F. vesca* likely being the A genome donor. The B genome donor has not been clearly elucidated, although

Table 4 Strawberry (*Fragaria*) species of the world. $2n = 2x = 14^{(a)}$

Species	Ploidy	Location
<i>F. vesca</i> L.	2x	Worldwide

<i>F. chiloensis</i> (L.) Miller	8x	Western North America and Chile
<i>F. virginiana</i> Miller		North America
<i>F. iturupensis</i> Staudt		Iturup Island
<i>F. × ananassa</i> Duchesne in Lamarck		Worldwide

^(a) According to Staudt, *F. nipponica* and *F. yesoensis* are the same species

molecular evidence is accumulating that Japanese *F. innumae* may be it (Davis and DiMeglio, 2004).

The most likely origin of the octoploids is that they originated in northeastern Asia when *F. vesca* combined with other unknown diploids, and the polyploid derivatives then migrated across the Bering Strait and dispersed across North America (Hancock, 1999). It is possible that *F. chiloensis* and *F. virginiana* are extreme forms of the same biological species, separated during the Pleistocene, which subsequently evolved differential adaptations to coastal and mountain habitats. The two species are completely interfertile, carry similar cpDNA restriction fragment mutations (Harrison *et al.*, 1997) and have very similar nuclear internal transcribed spacer (ITS) regions (Potter *et al.*, 1997).

Polyploidy in *Fragaria* probably arose through the unification of $2n$ gametes, as several investigators have noted that unreduced gametes are relatively common in *Fragaria* (Hancock, 1999). Staudt (1984) observed restitution in microsporogenesis of a F_1 hybrid of *F. virginiana* × *F. chiloensis*. In a study of native populations of *F. chiloensis* and *F. vesca*, Bringhurst and Senanayake (1966) found frequencies of giant pollen grains to be approximately 1% of the total.

Over 10% of the natural hybrids generated between these two species were the result of unreduced gametes.

The inheritance patterns of the octoploids are somewhat in dispute. Lerceteau-Köhler *et al.* (2003) concluded that *F. × ananassa* has mixed segregation ratios using amplified fragment length polymorphism (AFLP) markers, as they found the ratio of coupling versus repulsion markers fell between the fully disomic and polysomic expectations. However, two other studies evaluating isozyme, simple sequence repeat (SSR) and restriction fragment length polymorphism (RFLP) segregation observed predominantly disomic ratios, indicating that the octoploid strawberry is completely diploidized (Arulsekaran and Bringhurst, 1981; Ashley *et al.*, 2003).

While there appear to be some barriers to interfertility among the diploid strawberries, they all can be crossed to some extent, and meiosis in the hybrids is regular, even in cases where the interspecific hybrids are sterile (Hancock, 1999). There are at least three overlapping groups of diploid species that are interfertile (Bors and Sullivan, 1998): (1) *F. vesca*, *F. viridis*, *F. nubicola*, and *F. pentaphylla*, (2) *F. vesca*, *F. nilgerrensis*, *F. daltoniana*, and *F. pentaphylla*, (3) *F. pentaphylla*,

F. gracilis, and *F. nipponica*. *Fragaria iinumae* may belong in group 3 or in an additional group, as no fertile seeds have been recovered when it was crossed with either *F. vesca*, *F. viridis*, or *F. nubicola*, but it has not been crossed with enough other species to accurately classify it. *Fragaria iinumae* does, however, have a glaucous leaf trait that is unique among the diploids, and its chloroplast RFLPs cluster it with *F. nilgerrensis* in a group that is isolated from the rest (Harrison *et al.*, 1997).

The incorporation of traits from a number of lower ploid species has been accomplished through pollinations with native unreduced gametes or by artificially doubling chromosome numbers. The utility of this approach has been shown for a wide range of species in *Fragaria* and in the related genus *Potentilla* (Hancock, 1999). Particular success in incorporating lower ploidies into the background of *F. × ananassa* has come through combining lower ploidy species and then doubling to the octoploid level (Bors and Sullivan, 1998).

1.3 Economic Importance

1.3.1 Blueberry and cranberry

The highbush blueberry is by far the most important commercial crop in *Vaccinium*, with over 85 000 tons of highbush fruits being produced annually on over 20 000 ha (USDA Agricultural Statistics). The estimated area of rabbiteye production is currently about 3000 ha, with half the acreage in Georgia. The total annual production is over 5500 tons. Half-high production is restricted to a few hundred hectares in Minnesota and Michigan. Annual production of lowbush blueberries ranges from 25 000 to 40 000 tons on about 40 000 ha in primarily Maine and the Maritime provinces of eastern Canada. Cranberry production is about 170 000 tons annually on 9000 ha in Massachusetts, Oregon, and Michigan.

Blueberries and bilberries are eaten both as dessert fruits and in processed forms. About 50% of the highbush crop is marketed fresh and the remainder is processed. Blueberries are used primarily in pie fillings, yogurts, ice cream, and prepared muffin and pancake mixes. Syrups, jams, and preserves are also produced, but in limited quantities. The juice of blueberries is rarely

consumed directly as it has a very strong flavor and dark color. The fruits of cranberries are very tart and for this reason are mostly processed into juices or processed in baked goods. Blueberries and cranberries are sometimes added to dried products after dehydration using an explosion-puffing process.

An average blueberry fruit is composed of approximately 83% water, 0.7% protein, 0.5% fat, 1.5% fiber, and 15.3% carbohydrate (Hancock *et al.*, 2003). Cranberries contain 88% moisture, 0.2% protein, 0.4% fat, 1.6% fiber, and 7.8% carbohydrate. Blueberries have 3.5% cellulose and 0.7% soluble pectin, while cranberries contain 1.2% pectin. The total sugars of blueberries amount to more than 10% of the fresh weight, and the predominant reducing sugars in blueberries are glucose and fructose, which represent 2.4%. The edible portion of the cranberry is composed of 2.66% glucose, 0.74% fructose, and 0.14% sucrose. Its pulp contains measurable amounts of lignin, glucose, arabinose, and xylose.

The overall acid content of *Vaccinium* fruit is relatively high. Ripe cranberries range from 2% to 3%, while blueberries fall in the range of 1–2%. The primary organic acid in blueberries is citric acid (1.2%). They also contain significant amounts of ellagic acid, a compound thought to reduce the risk of cancer (Maas *et al.*, 1991). The cranberry contains high levels of several organic acids, including quinic (1.3%), citric (1.1%), malic (0.9%), and benzoic (0.6%). Ingestion of cranberries leads to increased acidity of the urine through conversion of its high quinic and benzoic acid contents to hippuric acid by the body. The high acidity and possible antibacterial effects of hippuric acid may relieve urinary tract infections and reduce some types of kidney stones.

Compared to other fruits and vegetables, blueberries and cranberries have intermediate to low levels of vitamins, amino acids, and minerals (Hancock *et al.*, 2003). Blueberries contain 22.1 mg of vitamin C per 100 g of fresh weight and cranberries contain 7.5–10.5 mg. Blueberries are unusual in that arginine is their most prominent amino acid.

In general, blueberries are one of the richest sources of antioxidant phytonutrients among the fresh fruits, with total antioxidant capacity ranging from 13.9 to 45.9 μmol Trolox equivalents per gram fresh berry (Ehlenfeldt and Prior,

2001; Connor *et al.*, 2002a, b). Berries from the various *Vaccinium* species contain relatively high levels of polyphenolic compounds, with chlorogenic acid predominating. Total anthocyanins (ACYs) in blueberry fruit range from 85 to 270 mg per 100 g, and species in the subgenus *Cyanococcus* carry the same predominant ACYs, aglycones, and aglycone-sugars, although the relative proportions vary (Ballington *et al.*, 1988). The predominant ACYs were delphinidin-monogalactoside, cyanidin-monogalactoside, petunidin-monogalactoside, malvidin-monogalactoside, and malvidin-monoarabinoside.

Among the other *Vaccinium*, cranberries have total ACYs varying from 25 to 100 mg per 100 g fruit, with the most important ACYs being cyanidin-3-monogalactoside, peonidin-3-monogalactoside, cyanidin-3-monoarabinoside, and peonidin-3-monoarabinoside. The various *Ericaceae* species also contain appreciable amounts of several carotenoids.

The major volatiles contributing to the characteristic aroma of blueberry fruit are *trans*-2-hexanol, *trans*-2-hexanal, and linalool (Hancock *et al.*, 2003). The predominant volatiles in the bilberry are *trans*-2-hexanal, ethyl-3-methyl butyrate, and ethyl-2-methyl butyrate. In the cranberry, 2-methyl butyrate is rare, but α -terpineol predominates. Benzaldehyde also contributes to the aroma of the cranberry.

1.3.2 Cane fruit

Raspberries are grown in 37 countries on over 70 000 ha; worldwide production is over 414 000 metric tons, with a 38% increase over the last 10 years (FAO, 2002). Russia and Serbia now account for almost 50% of the worldwide raspberry production, with the United States having about 13% and Poland about 11%. Over 95% of the raspberry hectareage is under red cultivars. The major production areas in North America are the Pacific Northwest (Oregon, Washington, and British Columbia), California, and the eastern United States (New York, Michigan, Pennsylvania, and Ohio). Mexico and Chile export significant amounts of raspberries to North America from November to May.

The highest production of blackberries and hybrid berries is in North America (42%) and Europe (30%) (Strik *et al.*, 2006). Serbia, Oregon, Hungary, and California are the leading production regions, with significant hectareage also being found in China, Guatemala, Spain, Canada, and Australia. Worldwide production of blackberries and hybrid berries is over 140 000 metric tons on about 20 000 ha. Worldwide blackberry production has almost doubled over the last 10 years.

Raspberries are commonly eaten fresh, individually quick frozen, and processed into juice, yogurt, jam, and flavorings. Raspberry juice is generally blended with apple, pear, or grape juice, as the flavor is too intense for direct consumption. Most blackberries and hybrid berries are processed into preserves, jams, jellies, and pastry fillings. Quick-frozen blackberries are also gaining in popularity.

Raspberry fruits are composed primarily of water (87%), with pectins making up 0.1–1.0% of the remaining soluble fraction (Green, 1971). A typical raspberry is composed of 5–6% sugar, with the main sugars being glucose, fructose, and to a lesser degree sucrose. One hundred gram of fresh raspberries have 0.42–1.40 g of protein, 0.20–0.55 g of fat, 5.8–11.6 g of carbohydrate, 3.0–7.4 g of fiber, 0.40–0.51 g of ash, and contain 31–49 kcal of food energy.

Raspberry fruits contain only small amounts of most vitamins, although vitamin C is found in significant levels. The predominant amino acids include alanine, asparagine, aspartic acid, glutamic acid, γ -aminobutyric acid, leucine, serine, and valine. Raspberry juice contains from 0.10% to 0.14% polyphenols; most of these being catechin, chlorogenic, ferulic, and neochlorogenic acids. The color of raspberries is imparted primarily by ACYs, with cyanidin and pelargonidin glucosides predominating (Jennings and Carmichael, 1980). Up to six sugars may be attached at the 3-position-one monoglycoside, three diglycosides and two triglycosides. The cyanidin glucosides predominate in raspberries and blackberries.

A considerable amount of recent research has documented variation patterns in the antioxidant capacity of *Rubus* species and crosses. Deighton *et al.* (2000) measured the antioxidant properties of domesticated and wild species, along with total phenol, ACY, and ascorbic acid contents. Antioxidant capacities ranged from 0 to 25.3 μ mol

Trolox equivalents per gram, with *R. caucasicus* having the highest values. Ascorbic acid and ACYs had only a minor influence on antioxidant capacity. Moyer *et al.* (2002) found that the western blackberry species *R. ursinus* and its derivatives were higher in antioxidant capacity than the eastern blackberry cultivars and most European *Rubus* species. In a comparison of antioxidant capacity in cultivars of thornless blackberry, red raspberry, and black raspberry, Wang and Lin (2000) found black raspberries to have the highest antioxidant capacity, followed by blackberries and red raspberries.

A large number of volatile compounds are found in raspberry fruit (Shamaila *et al.*, 1993; Moore *et al.*, 2002). One of the most abundant ketones, 1-(p-hydroxyphenyl)-3 butanone produces an odor very characteristic of raspberry (Larsen and Poll, 1990). Other important volatile compounds include alcohols, acids, esters, carbonyls, and naphthalene. Numerous aromas have also been identified in blackberry, although no single volatile has been described as characteristically blackberry (Klesk and Qian, 2003).

1.3.3 Strawberry

Strawberries are the most important soft fruits grown worldwide. The cultivated strawberry, *F. × ananassa*, is a regular part of the diets of millions of people and is cultivated in all arable regions of the globe from the arctic to the tropics. Annual world production of strawberries has steadily grown through the ages, with quantities doubling in the last 20 years to over 3.2 million metric tons. Most of the production is located in the northern hemisphere (98%), but there are no genetic or climatic barriers preventing greater expansion into the southern hemisphere.

The United States is the leading producing nation with approximately 25% of the world's crop, followed by Spain, Japan, Poland, Italy, and the Korean Republic. California dominates the strawberry industry in the United States with over 80% of the total production. The industries in Spain, the Korean Republic, and the United States have grown steadily over the last two decades, while production in Japan, Italy, and Poland have declined in the last decade, after dramatic increases in the 1970s and 1980s.

The strawberry is widely appreciated for its delicate flavor, aroma, and nutritional value. Ripe strawberries are composed of approximately 90% water and 10% total soluble solids (Hemphill and Martin, 1992), and contain numerous important dietary components. They are extremely high in vitamin C and a standard serving of strawberries (10 fruit) supplies 95% of the recommended dietary requirements (National Academy of Sciences, 1989; Maas *et al.*, 1996). The main soluble sugar components in strawberries are glucose and fructose, which are over 80% of the total sugars and 40% of the total dry weight (Wrolstad and Shallenberger, 1981). The primary organic acid is citric acid, which composed 88% of the total acids (Green, 1971). The strawberry also contains significant levels of ellagic acid, which is thought to be an anticarcinogenic (Maas *et al.*, 1991).

Red color develops through the production of ACYs, primarily pelargonidin-3-glucosidase (Wrolstad *et al.*, 1970; Kalt *et al.*, 1993), although at least eight pelargonidin- and two cyanidin-based ACYs have been detected in strawberry juice (Bakker *et al.*, 1994). Cyanidin 3-glucoside is the second most common ACY. The total concentration of ACYs varies 16-fold across cultivars, and there is some variation in ACY composition, although no clear associations between individual ACYs and color have been observed (Bakker *et al.*, 1994).

Glucose, fructose, and sucrose are the major soluble sugars found in the fruit of strawberries during all stages of ripening. Glucose and fructose are found in almost equal concentrations (Maas *et al.*, 1996), and they rise continuously during fruit development from 5% in small green fruit to 6–9% in red berries (Kader, 1991). Sucrose levels are generally much lower, and show little accumulation until about the middle of fruit development (Forney and Breen, 1986). Invertases probably play an important role in determining sweetness, by regulating hexose and sucrose levels (Ranwala *et al.*, 1992; Manning, 1998).

Strawberry flavor is a complex combination of sweetness, acidity, and aroma. The most intensely flavored fruits generally have high levels of both titratable acidity (TA) and soluble solids, while the blandest fruit are low in both these components (Kader, 1991). The primary components of flavor have not been completely elucidated, but strawberry aroma is thought to originate from a

complex mixture of esters, alcohols, aldehydes, and sulfur compounds (Schreier, 1980; Dirinck *et al.*, 1981; Pérez *et al.*, 1996). Hundreds of volatile esters have been correlated with strawberry ripening and aroma development, with methyl- and ethyl-esters of butanoic and hexanoic acids being among the most prevalent (Larsen and Poll, 1992; Pérez *et al.*, 1992, 1996). Other components in high concentration are trans-2-hexenyl acetate, trans-2-hexenal, trans-2-hexenol, and 2,5-dimethyl-4-hydroxy-3(2H)-furanone (furanol). Concentrations of these volatiles vary widely among cultivars and produce large variations in aroma quality (Hirvi, 1983; Shamaila *et al.*, 1992; Pérez *et al.*, 1996, 1997).

Aroma and fragrance content also varies across species. Several researchers consider 2,5-dimethyl-4-hydroxy-3(2H)-furanone (furanol) and 2,5-dimethyl-4-methoxy-3(2H) furanone (mesifurane) as being particularly important aroma contributors (Pyysalo *et al.*, 1979; Larsen and Poll, 1992; Sanz *et al.*, 1994; Pérez *et al.*, 1996). The wild species *F. vesca* and *F. virginiana* have much stronger aroma than the cultivated types (Hirvi and Honkanen, 1982). *F. vesca* contains high amounts of ethyl-acetate, but low amounts of methyl butyrate, ethyl butyrate, and furanone. *Fragaria nilgerrensis* contains high levels of ethyl acetate and furanone, but low levels of methyl butyrate and ethyl butyrate. Hybrids between *F. vesca* and *F. × ananassa* have intermediate levels of fragrance and aroma, while crosses between *F. nilgerrensis* and *F. × ananassa* more closely resemble *F. nilgerrensis*.

1.4 Traditional Breeding

1.4.1 Blueberry and cranberry

Blueberry breeding is a very recent development. Highbush breeding began in the early 1900s in New Jersey, with the first hybrid being released in 1908 by F. Coville of the United States Department of Agriculture (USDA). He conducted the fundamental life history studies of the blueberry that served as the basis of cultivation such as soil pH requirements, cold and day-length control of development, pruning strategies, and modes of propagation. Working with Elizabeth White and others, he collected several outstanding wild clones of *V. corymbosum* and *V. angustifolium*,

which he subsequently used in breeding improved types. Over 75% of the current blueberry acreage is still composed of his hybrids, most notably “Bluecrop”, “Jersey”, “Weymouth”, “Croatan”, “Blueray”, “Rubel”, and “Berkeley.”

G. Darrow took over the USDA program and made important contributions on the crossability and speciation of the native species, and began working on the development of southern highbush types with R. Sharp in Florida. Out of that work came the important cultivar Sharpblue, which was grown commercially until very recently. P. Lyrene took over the breeding work when R. Sharp retired and has released a number of important cultivars including “Misty” and “Star.” These cultivars are known for their high fruit quality and plant vigor.

A. Draper eventually took over the breeding work at the USDA and focused on mixing the genes of most wild *Vaccinium* species into the cultivated highbush background. He released a prodigious number of southern and northern highbush cultivars, with improved fruit color and firmness, smaller pedicle scars, and higher productivity (Hancock and Galletta, 1995). His “Duke” and “Elliott” have been major successes, and several of his other cultivars show great promise including “Nelson” and “Legacy.”

Numerous other highbush breeding programs have made substantial contributions over the last 50 years. S. Johnson at Michigan State University was one of the first highbush breeders outside the USDA and worked hard to improve the cold tolerance of highbush by crossing it with *V. angustifolium*. The strategy did not work, but he and his replacement, J. Moulton, produced two important cultivars, “Bluejay” and “Northland.” J. Hancock is now at MSU and has released three new northern highbush cultivars that show high promise, “Aurora”, “Draper” and “Liberty.” J. Moore and now J. Clark in the University of Arkansas have maintained a healthy interest in southern wild species as gene donors, and recently released “Ozarkblue”, a very high quality late type. In North Carolina, J. Ballington has worked at the climatic interface between northern and southern highbush types, and has generated a number of exciting cultivars including the Southern highbush type “O’Neal”, and the likely intermediate types “Reveille”, “Arlen” and “Summit.”

Several other highbush breeding projects have produced attractive cultivars. The ones making

the biggest impact are “Brigitta Blue” selected by D. Jones and R. Bell in Australia from open-pollinated seeds collected by Johnston, and “Reka” and “Nui” released by N. Patel in New Zealand.

Rabbiteye breeding was initiated in the 1940s by G. Darrow in collaboration with O. Woodward at the Georgia Agricultural Experiment Station and E.B. Morrow at the North Carolina Experiment Station. This work was continued by M. Austin and S. Nesmith in Georgia, G. Galletta and Ballington in North Carolina, and R. Sharp and P. Lyrene in Florida. These breeding programs have resulted in significant improvements in fruit color, size, texture, and attractiveness over the original wild selections. The most important cultivars have been “Tifblue” (1955) and “Climax” (1975) from Georgia and “Powderblue” and “Primier” (1978) from North Carolina.

Cranberries have been bred sporadically since the mid-1900s, although most of the crop is still produced from the wild selections “Early Black”, “Howes”, “McFarlin” and “Searles”. In 1929, the USDA began a cooperative cranberry breeding project between the New Jersey, Massachusetts, and Wisconsin Departments of Agriculture. Out of this program came “Pilgrim” with improved size, color (purplish red), keeping quality, productivity, and resistance to the blunt-nosed leafhopper and “Stevens” with improved color (deep red), firmness, and resistance to softening. “Crowley” was introduced from the Washington Agriculture Station in the 1960s as a better pigmented replacement for “McFarlin.” Cranberry breeding programs are currently being conducted at Rutgers University (N. Vorsa) and the University of Wisconsin (E. Zeldon and B. McCown).

Little breeding work has been conducted on lowbush blueberries, although the lowbush types have been hybridized to produce “half-highs”. The major cultivars of this type are “Northland” developed by Johnston in Michigan in the 1960s and “North Country” developed more recently by J. Luby in Minnesota. The “half-highs” have much higher yields and larger fruit than lowbush, but have low enough stature to be protected by snow in areas with extreme winter cold.

Blueberries are all primarily outcrossing with varying levels of self-fertility, depending on species and genotype. In general, northern highbush blueberries have the highest levels of self-fertility,

followed by southern highbush and rabbiteye. Northern highbush are generally planted in solid blocks, although having a pollinator would be beneficial for most cultivars. Southern highbush and rabbiteye need pollinators, and alternate row plantings are recommended. Lowbush fruit is harvested from highly variable native stands, and as such considerable natural cross-pollination occurs. Cranberries are self-fertile, but cross-pollination can enhance seed production (Galletta and Ballington, 1996).

Blueberries and cranberries are asexually propagated through cuttings and tissue culture. All breeding programs have relied primarily on pedigree breeding where elite parents are selected each generation for intercrossing. Interspecific hybridization has played a major role in the development of highbush blueberries. Probably the most important success was the transfer of a low chilling requirement from the diploid *V. darrowii* to the northern tetraploid highbush *V. corymbosum* via unreduced gametes. One hybrid produced by Draper, US 75 (Fla 4B × Bluecrop), was completely fertile and is the source of the low chilling requirement in many of the southern highbush cultivars.

Several other strategies have been used to incorporate the genes of native species into the cultivated highbush background. *V. corymbosum* has been crossed with *V. angustifolium* to produce “half-high” types with greater winter tolerance than highbush. Draper produced interspecific tetraploid hybrids of *V. myrsinites* × *V. angustifolium* that could be directly crossed with highbush. He colchicine-doubled diploid hybrids of *V. myrtilloides* × *V. corymbosum* and then crossed this hybrid with *V. corymbosum*. He also generated numerous hybrids of diploid and polyploid species and the most fertile were ones were used as breeding parents. Interspecific crosses have been attempted among the other genera of *Vaccinium*, but with only limited utility (Luby *et al.*, 1991).

Most of the highbush types now being released are complex hybrids. Some of the most dramatic examples are “O’Neal” that contains genes from the four species (*V. corymbosum*, *V. darrowii*, *V. ashei*, and *V. angustifolium*) and “Sierra” that possesses the genes of five species (*V. corymbosum*, *V. darrowii*, *V. ashei*, *V. constablaei*, and *V. angustifolium*). “Biloxi” contains the genes from

five species (*V. corymbosum*, *V. darrowii*, *V. ashei*, *V. atrococcum*, and *V. angustifolium*), and has fewer *V. corymbosum* than non-*V. corymbosum* genes in its genome.

The current goals of southern highbush breeders are to obtain early ripening types with high plant vigor, disease resistance, and a later bloom (particularly in Florida). Established breeding lines are being used for this purpose, along with hybrids derived from native *V. ashei*, *V. elliottii*, and *V. darrowi*. Rabbit-eye breeders hope to expand harvest dates, improve flavor, and improve storage life. The northern highbush breeders are concentrating on flavor, longer fruit storage, expanded harvest dates, disease and pest resistance, and machine harvestability. Established breeding lines are being used by northern highbush breeders, along with complex hybrids made up of *V. darrowi*, *V. angustifolium*, *V. constablei*, and most of the other wild species. Even though it has limited winter hardiness, *V. darrowii* has proven to be an interesting parent in colder climates, because it passes on a powderblue color, firmness, high flavor, heat tolerance, and potential upland adaptations. Cranberry breeders are focusing on early maturing fruit, uniform large size, intense color, keeping quality, high productivity, and plant vigor.

1.4.2 Cane fruit

The first formal breeding work on red raspberries was begun in North America. The most enduring cultivar from this early period was “Latham”, which was introduced in 1914 by the Minnesota Fruit Breeding Farm (Jennings, 1988). It was the leading cultivar in eastern North America until 1930 when “Newburgh” (Geneva Experiment Station) and “Chief” (Minnesota Fruit Breeding Farm) were released. “Latham” and “Chief” ultimately became important in eastern Europe where hardiness was at a premium.

Another important early cultivar was “Cuthbert”, found in New York as an accidental hybrid of “Hudson River Antwerp” (*R. idaeus*) and a native (*R. strigosus*). It was a dominant cultivar from the 1940s to the 1980s. Two other early cultivars that had a major impact were “Lloyd George” found in the wild in 1919 by J. J. Kettle in Kent, England and “Pyne’s Royal” released in 1913 by T.B. Pyne of Topsham Nurseries. Later

cultivars that became dominant were “Willamette” and “Canby”, which were developed by George Waldo and released in the 1940s, “Malling Jewel” introduced in 1950 by Grubb at East Malling Research Station, “Meeker”, which was introduced by C.D. Swartz from Washington in 1967, and “Glen Clova” released by D. Jennings in 1969 from the Scottish Horticulture Research Institute.

“Lloyd George” has been a particularly important parent, being in the direct ancestry of 32% of the North American and European cultivars in 1970 (Oydin, 1970). This cultivar contributed several important traits including primocane fruiting, large fruit size, and resistance to the North American aphid. Jennings (1988) speculated that the success of “Lloyd George” hybrids “was possibly achieved because they combined the long conical shape of “Lloyd George” receptacle with the more rounded shape of the American raspberries”. A key example of such a hybrid is “Willamette”, which is a cross of “Newburg” × “Lloyd George” and has dominated the industry in western North America for over a half century. Other especially important cultivars have been the florican fruiting types “Malling Jewel” from the United Kingdom, “Glen Moy” and “Glen Ample” from Scotland, “Chilcotin”, “Skeena”, “Chilliwack”, “Tulameen”, and “Malahat” from British Columbia and the primocane fruiting “Heritage” from New York and “Autumn Bliss” and “Autumn Britten” from the United Kingdom.

The most active black raspberry breeding was conducted at Geneva, New York by R. Wellington. A number of important cultivars were released from there in the 1920s and 1930s including “Dundee”, “Naples”, “Rachel”, “Bristol” and “Evans” (Jennings, 1988). Bristol is still an important cultivar, known for its vigor and fruit size. George Slate followed Wellington and selected “Allen”, “Huron” and “Jewel” in the 1950s and 1960s, all noted for their large fruit. Another important cultivar, Munger, was released from Oregon in 1897.

Most of the early cultivars of blackberries were selected from the wild. The earliest systematic breeding of blackberries was done by Judge Logan in California in the late 1880s (Jennings, 1988). He selected the hybrid “Loganberry” from the natural cross of “Aughinbaugh” × “Red Antwerp” and “Mammoth” (“Black Logan”)

from “Aughinbaugh” × “Texas Early”. Darrow and Waldo of the USDA developed a number of popular blackberry cultivars for the Pacific Northwest in the middle of the 20th century including “Pacific”, “Cascade”, “Chehalem”, “Olallie”, and “Marion.” “Marion” is still widely grown, known for its rich flavor and high productivity. The cultivar “Silvan” was selected in 1984 in Victoria, Australia from seed generated in Oregon between “Marion” and a Bosenberry hybrid (McGregor and Kroon, 1984). It has much higher yields than “Marion” and large, excellent flavored fruit.

The most successful, early breeding work on blackberries in the eastern United States was done at Geneva, New York by Slate in the 1950s who introduced the cultivars “Hedrick” and “Darrow.” A significant later advancement was made when Scott and Ink (1966) at the USDA at Beltsville, Maryland transferred the recessive gene for spinelessness from the British cultivar “Merton Thornless” to generate “Thornfree” and “Darrow.” Later releases from Maryland were “Dirkson Thornless”, “Black Satin”, “Hull Thornless”, and “Chester Thornless.” Some of the newer blackberry releases that have made a major impact in colder climates are “Loch Ness” from Scotland and “Ćaćanska Bestrna” from Serbia. The most important blackberry cultivars for hot climates are currently “Brazos” from Texas, “Cherokee”, “Navaho”, and “Arapaho” from Arkansas, and “Tupy” from Brazil (Strik *et al.*, 2006).

Today, the major objectives of raspberry and blackberry breeding programs are high quality, good yields, suitability for shipping if fresh market, machine harvestability, and suitability for processing for the industrial market, adaptation to local environments, and improved pest and disease resistance (Finn and Knight, 2002). Resistance to *Phytophthora fragariae* is a widespread goal in all raspberry breeding programs. In Europe, breeders are most concerned with cane *Botrytis*, spur blight, and cane spot. Raspberry bushy dwarf virus (RBDV) is a major concern in the Pacific Northwest where RBDV has reached epidemic proportions. The development of spineless erect and trailing types is of paramount importance in raspberries. Efforts are also underway to develop raspberries that can tolerate hotter and more humid conditions and blackberries

that can flourish in colder conditions. High recent interest also revolves around developing primocane fruiting blackberries.

Wide hybridization has played a particularly important role in raspberry breeding. In fact, some of the most important breeding progress was made in the 19th century by crossing North American *R. strigosus* with European *R. idaeus*, and genes from at least six other species in *Idaeobatus* have been incorporated into red raspberry cultivars including *R. occidentalis*, *R. cockburnianus*, *R. biflorus*, *R. kunzeanus*, *R. parvifolius*, and *R. pungens oldhamii*, along with two *Cylactis* species (*R. articus* and *R. stellatus*) and an *Anoplobatus* species (*R. odoratus*) (Daubeny, 1996). Finn and Knight (2002) report that over 70 *Rubus* species are now being evaluated as possible parents.

Blackberry breeding also has had a rich tradition of interspecific hybridization, with different ploidy levels often being crossed. Most blackberries are tetraploid, but ploidy levels range from diploid to $2n = 14x = 98$ (Thompson, 1995a, b). The “Loganberry” is an allohexaploid derived from a reduced gamete of octoploid *R. ursinus* and an unreduced gamete of diploid *R. idaeus* (Crane, 1940; Thomas, 1940). Other interspecific polyploidy hybrids were selected in the late 1800s and early 1900s including the “Laxtonberry” (septaploid of “Loganberry” × the raspberry “Superlative”), “Phenomenal Berry” (hexaploid of “Aughinbaugh” × the raspberry “Cuthbert”), “Youngberry” (septaploid of “Phenomenal Berry” × a dewberry hybrid of *R. baileyanus* × *R. argutus*), and Boysenberry (septaploid of “Loganberry” × a trailing blackberry).

Raspberries are generally outcrossing, but some blackberries are apomictic, which complicates breeding. Darrow and Waldo (1933) reported that crosses with “Thornless Evergreen” produced 87% apomictic progeny, while Hall *et al.* (1986) found 94% apomicts in their crosses of “Thornless Evergreen”. The hybrid offspring are very difficult to identify without biochemical or molecular markers.

1.4.3 Strawberries

The dessert strawberry is an outcrossed crop that is relatively sensitive to inbreeding (Morrow and Darrow, 1952; Melville *et al.*, 1980), and it

can be asexually propagated by runners, so most modern varietal improvement programs have been based on pedigree breeding where elite parents are selected each generation for intercrossing. The germplasm base of strawberry is considered to be relatively narrow (Sjulin and Dale, 1987), but if adequate population sizes are maintained, changes in levels of homozygosity across generations appear to be minimal (Shaw, 1995). Since highly heterozygous genotypes can be propagated as runners, few breeding programs have developed hybrid cultivars using inbred lines, although some cultivars have been generated in this manner.

Selfing has been successfully employed in a number of instances to concentrate genes of interest (Hancock *et al.*, 1996) and backcrossing has been used occasionally to incorporate specific traits. Barritt and Shanks (1980) moved resistance to the strawberry aphid from native *F. chiloensis* to *F. × ananassa*. Bringham and Voth (1978, 1984) transferred the day neutrality trait from native *F. virginiana* spp. *glauca* to *F. × ananassa*. Approximately three generations were necessary to restore fruit size and yield to commercial levels.

Formal strawberry breeding was initiated in England in 1817 by Thomas A. Knight (Darrow, 1966; Wilhelm and Sagen, 1974). He was one of the first systematic breeders of any crop, and used clones of both *F. virginiana* and *F. chiloensis* in his crosses. He produced the famous “Downton” and “Elton” cultivars, noted for their large fruit, vigor, and hardiness. Michael Keen, a market gardener near London, also became interested in strawberry improvement about this time and developed “Keen’s Imperial” whose offspring, “Keen’s Seedling” is in the background of many modern cultivars. This cultivar dominated strawberry acreage for close to a century.

Thomas Laxton of England was the most active breeder during the later part of the 18th century and released a number of important cultivars including “Noble” and “Royal Sovereign.” These two cultivars were grown on both sides of the Atlantic Ocean, and were popular until the middle of the 20th century. “Nobel” was known for its earliness, cold hardiness, and disease resistance. “Royal Sovereign” was popular because of its earliness, productivity, flavor, attractiveness, and hardiness.

Charles Hovey, of Cambridge, Massachusetts, produced the first important North American

cultivar, “Hovey”, by crossing the European pine strawberry, “Mulberry” with a native clone of *F. virginiana* in 1836. It was the first cultivar of any fruit to come from an artificial cross in America and for a while made the strawberry the major pomological product in the country (Hedrick, 1925).

Albert Etter of California developed dozens of cultivars around the turn of the century utilizing native *F. chiloensis* clones (Fishman, 1987). His most successful cultivar was Ettersburg 80 (1910), which was widely grown in California, Europe, New Zealand, and Australia. Renamed as “Huxley”, it was still popular in England as late as 1953. Ettersburg 80 was extremely drought resistant, of outstanding dessert and jam quality due to its solid bright red color, and was unusually hardy for a California type. Other outstanding Etter cultivars were “Ettersburg 121”, “Fendalcino” and “Rose Ettersburg.” While these releases were very successful as cultivars, they may have had their greatest impact as breeding parents. Most California cultivars (and many others) have an Ettersburg cultivar in their background (Darrow, 1966; Sjulin and Dale, 1987).

In the middle of the 20th century, a number of particularly successful breeding programs emerged in Scotland, England, Germany, and Holland. In Scotland, Robert Reid developed a series of red stele resistant cultivars utilizing American “Aberdeen” as a source of resistance. His cultivar “Auchincruive Climax” dominated acreage in Great Britain and northern Europe until its demise due to June yellows in the mid-1950s. In England, D. Boyle produced a large series of cultivars with the prefix “Cambridge”. “Cambridge Favorite” (1953) became the most important of the group and dominated the acreage in Great Britain by the 1960s. In Germany, R. von Sengbusch’s produced a “Senga” series, of which “Senga Sengana” (1954) became paramount. “Senga Sengana” was widely planted for its processing quality and is still important in Poland and other eastern European countries. In the Netherlands, H. Kronenberg and L. Wassenaar’s released several cultivars, of which “Gorella” (1960) made the greatest impact. It was noted for its size, bright red glossy skin, and red flesh. B. Meelenbroek who followed in this program released “Elsanta” (1981), considered the ideal fresh market cultivar for its bright color, flavor, and regular size.

Most of the breeding advances in the eastern United States have come from the USDA (Hancock, 1999). George Darrow at Beltsville, Maryland developed “Blakemore”, which became the major southern US cultivar in the mid-1930s and “Fairfax” was widely planted in the middle of this century from southern New England to Maryland and westward to Kansas. These two cultivars were used extensively in breeding, finding their way into the ancestry of a diverse array of cultivars grown in all parts of the United States. Other important releases from Darrow were “Pocahontas”, “Albritton”, “Surecrop” and “Sunrise”. D.H. Scott, A.D. Draper, and G.J. Galletta followed Darrow and released “Redchief” (1968), “Earliglow” (1975), “Allstar” (1981), and “Tribute” and “Tristar” (1981). All of these cultivars are still grown today, and Tribute and Tristar were the first day neutrals widely grown in the eastern United States. An active USDA breeding program has also been conducted at Corvallis, Oregon initially by Darrow, G.F. Waldo, and F.J. Lawrence, and now C. Finn. Some of the more important cultivars emerging from this program were “Siletz” (1955) and “Hood” (1965). “Hood” is considered the premier berry for processing.

Several other state and federal supported programs have released important cultivars in the United States and Canada. Some of the most significant ones from the United States were “Honeoye” and “Jewel” (New York), “Raritan” (New Jersey) and “Sweet Charlie” (Florida). From Nova Scotia came “Bounty”, “Glooscap”, and “Kent.”

H. Thomas and E. Goldsmith’s of the University of California released the important cultivars “Lassen” and “Shasta” in 1945. “Shasta” was widely grown in the central coast of California in the 1950s and 1960s because of its large size, firmness, and long season. “Lassen” was grown extensively in southern California about the same period, prized for its short rest period, and high productivity. R. Bringham and V. Voth took over the California-Davis program in the 1950s and generated a succession of internationally important, Mediterranean adapted cultivars including “Tioga” (1964), “Tufts” (1972), “Aiko” (1975), “Pajaro” (1979), “Chandler” (1983), “Selva” (1983), “Camarosa” (1992) and “Seascape” (1991). Most recently,

Doug Shaw has released “Diamonte” from this program.

The greatest concentration of breeding activity outside of Europe and the United States has been in Japan. Two very important cultivars were produced there: H. Fukuba’s “Fukuba” (1899), noted for its large size and high flavor (Darrow, 1966), and K. Tamari’s “Kogyoku” (1940), respected for its vigor, earliness, and fruit size (Mochizuki, 1995). “Fukuba” was the most important cultivar in forcing culture until the early 1970s. “Kogyoku” was one of the leading field grown cultivars after World War II, until it lost importance to the American import “Donner” in the 1950s.

1.5 Limitations of Conventional Breeding and Rationale for Transgenic Breeding

Since blueberries, cane fruits, cranberries, and strawberries are all asexually propagated, transgenic breeding could be used to rapidly introduce individual genes of interest without changing the inherent desirable characteristics of existing cultivars. To date, however, transformation technologies have been little utilized in these crops.

Resistance has been found for many of the important pest and disease problems in the small fruit crops, but in many cases the resistance is quantitative. This makes it difficult to incorporate multiple resistances into a new cultivar via hybridization and at the same time maintain high fruit quality and yield. The incorporation of transgenics that produce high levels of simply inherited resistance to these diseases would be highly beneficial, particularly if the transgenes are effective against multiple pests and/or diseases. There are also a few instances where no known resistance to a major disease or pest exists. In these cases, transgenic approaches might prove to be the only route to provide needed variability.

Small fruits are grown across a wide environmental zone, but several abiotic factors commonly limit their productivity, such as salinity, frost, and cold. As with disease and pest resistance, there are often sources of resistance available to these abiotic stresses, but in many cases the amount of variability among improved genotypes is low and the inheritance is quantitative. More variability can often be found in wild populations,

but at least three generations of backcrossing are necessary to approach commercial quality fruit. These factors have made it very difficult to improve resistance to salinity, frost, and cold without negatively impacting on fruit quality and yield. The incorporation of single transgenes improving these traits would greatly speed the development of genotypes with expanded abiotic tolerances.

1.5.1 Blueberry and cranberry

Blueberries are subject to a wide array of diseases. Probably the most widespread problems in highbush blueberry are mummy berry (*Monilinia vaccinii-corymbi* (Reade), blueberry stunt, blueberry shoestring virus, stem blight (*Botryosphaeria dothidea* (Mouq. Ex Fr.) Ces and de Not.), stem canker (*Botryosphaeria cortices* Demaree and Wilcox), *Phytophthora* root rot (*Phytophthora cinnamomi* Rands), *Phomopsis* canker (*Phomopsis lokoyae*), botrytis fruit rot (*Botrytis cinerea* Ters. Ex Fr.), and anthracnose fruit rot (*Colletotrichum gloeosporioides* (Penz.) Penz and Sacc.). Rabbiteye blueberries are much more resistant to diseases than highbush types, with only botrytis blossom and twig blight, stem blight and mummy berry being major problems. Lowbush is most negatively impacted by botrytis stem and twig blight and red leaf disease caused by *Exobasidium vaccinii* (Fckl.) Wor. The most serious disease problems of cranberry are fruit rots caused by *Guignardia vaccinii* Shear, *Godronia cassandrae* Peck, and *Ceuthospora lunata* Shear. Resistant or tolerant genotypes have been described for most of the above diseases, but the genetics of resistance has only been determined for *Phytophthora* root rot, *Phomopsis* canker, stem canker, and stem blight in blueberry (Luby *et al.*, 1991; Galletta and Ballington, 1996). Genetic resistance to these diseases is quantitative.

Several insects and arthropods do significant damage to highbush blueberries including blueberry maggot (*Rhagoletis pomonella* Walsh), sharp-nosed leafhopper (stunt vector) *Staphytopius magdalenensis* Prov., and blueberry aphid (shoestring virus vector) (*Illinoia pepperi* Mac. G.), cranberry fruit worm (*Acrobasis vaccinii* Riley), cherry fruitworm (*Graphditha packardi* Zell), and the plum curculio (*Conotrachelus nenuphar* Herbst). Lowbush and rabbiteye blueberries have

far fewer major pests than highbush types; however, significant damage is caused by cranberry fruitworm and stunt in rabbiteye blueberry, and maggot in lowbush. The most serious pests of cranberries are the leafhopper *Sclerorachus vaccinii*, which vectors false blossom disease, black root weevil *Brachyrhynchus sulcatus* Fabr., cranberry tip worm *Dasyneura vaccinii* Smith, black-headed fireworm *Rhopobota vacciniana* Pock, and the cranberry fruit worm. Very little variation in resistance has been reported to most of these pests except the sharp-nosed leafhopper, which was quantitatively inherited in *V. ashei*, but recessive in *V. elliotii* (Ballington *et al.*, 1993).

Among the abiotic factors limiting blueberries, high pH, temperature extremes, and insufficient soil drainage are the most important problems. The *Vaccinium* are “acid loving” and as such require soils below pH 5.8 for high vigor; they also do not tolerate flooded roots for more than a few days. Among the cultivars, there is little variation for these traits, although a number of wild species may have greater tolerance to soil pH (Luby *et al.*, 1991; Galletta and Ballington, 1996). Frost damage during the spring when blossoms begin to open is very prevalent across most of the highbush production regions and in the northern highbush production zones, winter cold often causes severe damage to flower buds and young shoots. There is little variation in frost tolerance among rabbiteye and highbush cultivars, although there is a considerable amount of quantitative variability in cold tolerance, with northern cultivars being hardier than southern ones. High temperature during harvest in the northern production areas often causes fruit softening and negatively impacts on storage life, but no formal screens have been made to search for variability in this characteristic. Cold hardiness is a complex interaction between rate of acclimation and deacclimation and deep winter tolerance.

In blueberries, the fruit characteristics most sought after are flavor, large size, light blue color (a heavy coating of wax), a small scar where the pedicel detaches, firmness, and a long storage life. Fruit firmness is probably paramount in determining the shelf life of blueberries, along with sugar to acid ratio. Considerable quantitative variability exists for all these traits, and some native species like *V. darrowi* have provided especially useful variability. High antioxidant capacity has

also become an important fruit quality parameter in blueberries. Considerable amounts of variability have been observed in this characteristic that is quantitatively inherited (Connor *et al.*, 2002a, b). ACY concentration is one of the major fruit quality factors in cranberries. Other important characteristics are uniform color, high aroma, firmness, glossiness, and ability to retain texture in storage. All of these characteristics appear quantitative in nature.

1.5.2 Cane fruit

The primary factor associated with low yields and degeneration of raspberry cultivars are viruses. The most important virus diseases are RBDV, raspberry yellow net (RYNV), black raspberry necrosis (BRNV), raspberry leaf mottle (RLMV), and raspberry leaf spot (RLSV). These four viruses are vectored by the aphids *Amphorophora idaei* Börner in Europe and *A. agathonica* Hottes in North America. Most cultivars are tolerant to raspberry yellow net and black raspberry necrosis (Jennings, 1988), but there are no published sources of resistance to RBDV, raspberry leaf mottle, and raspberry leaf spot.

Other important viruses are arabis mosaic virus and strawberry latent ringspot virus (SLRV) in England and southern Europe. These two viruses are vectored by *Xiphinema diversicaudatum* Micoletsky. The tomato ringspot virus (TRSV) is one of the most damaging viruses in North America, where it causes “crumbly fruit” and is vectored principally by the nematode *Xiphinema americanum* Cobb. Resistance and/or tolerance has been identified for strawberry latent ringspot, arabis mosaic, raspberry yellow net, black raspberry necrosis, and the two aphids (Daubeney, 1996), but no sources of resistance have been reported to raspberry leaf mottle, raspberry leaf spot or *X. americanum*. The resistance to arabis mosaic virus is regulated by a single gene (Jennings, 1964).

A number of fungal diseases cause serious damage to raspberries. The most important disease of fruit is gray mold, *Botrytis cinerea*. Most cultivars are susceptible to this disease, although quantitatively inherited sources of resistance are available (Jennings *et al.*, 1989). The most prevalent cane diseases of raspberries are midge

blight and cane blight. Midge blight is a disease complex instigated by damage from the raspberry midge, *Resseliella theobaldi* Barnes. Cane blight is caused by *L. coniothyrium*, which generally enters through wounds caused by mechanical harvesting. Spur blight (*Didymella applanata* (Niessl) Sacc) is a very important disease in the Pacific Northwest and eastern Europe. Only partially resistant genotypes have been identified to midge and cane blight (Jennings *et al.*, 1989; Williamson and Jennings, 1992). Hairy canes with gene *H* tend to be less affected by spur blight, with most sources of resistance being additive (Jennings, 1988; Williamson and Jennings, 1992).

Several other fungal problems commonly damage raspberries including cane spot or anthracnose (*Elsinoë veneta* (Burkh.) Jenkins), leaf spot (*Sphaerulina rubi* Demaree and Wilcox), yellow rust (*Phragmidium rubi-ideae* (DC.) Karst), and late yellow rust (*Pucciniastrum americanum* (Farl.) Arth.). Major resistance genes exist for these two fungal pathogens (Anthony *et al.*, 1986; Williamson and Jennings, 1992). Root rots are also often problems in both North America and Europe. The primary causal organism is *Phytophthora megasperma* Dreschsler in Europe and *Phytophthora erythroseptica* Pethyby in North America. Only quantitative resistance is known to these pathogens.

Blackberries are generally much more resistant to fungal diseases than raspberries. However, the following diseases can be quite important in North America: orange rust (*Gymnoconia pecking* (Howe) Trott.), anthracnose, rosette (double blossom) (*Cercospora rubra* (Wint.) Plakidas), leaf spot, and *Verticillium* wilt (*Verticillium albo-atrum* Reinke and Berth.). Purple blotch (*Septocytia ruborum* (Lib.) Petrak) is the most serious disease in Europe, while downy mildew (*Peronospora sparsa* Berk.) is very important in New Zealand. Quantitatively inherited resistance to all these diseases has been reported (Jennings, 1988; Williamson and Jennings, 1992).

The raspberry midge, mentioned above, and the raspberry beetle (*Byturus tomentosus* Degeer) are the most important insect pests of raspberry in Europe. The western raspberry fruitworm (*B. bakeri* Barber) and the eastern raspberry fruitworm (*B. rubi* Barber) are major problems in North America. Other serious pests across the world are the clay colored weevil (*Otiiorhynchus*

singularis L.), the black vine weevil (*Otiorhynchus sulcatus* Fab), and the two-spotted spider mite (*Tetranychus urticae* Koch) in the Pacific Northwest. Quantitative resistance has been described to the raspberry beetle (Jennings *et al.*, 1989), but there are no published reports on resistance to raspberry fruit worms, clay colored weevil, black vine weevil, and two-spotted spider mite.

Lack of winter cold tolerance limits the range of successful raspberry and blackberry cultivation in the continental climates of central and eastern Europe, and eastern and central North America. Blackberries are generally more sensitive to cold than raspberries, and black raspberries are less hardy than red raspberries. The inheritance of winter hardiness is under complex genetic control. Winter hardy raspberries have four key characteristics: (1) rapid hardening in the fall before severe temperatures occur, (2) long rest or deep dormancy making them resistant to temperature fluctuations in the spring, (3) the ability to re-harden if initial cold tolerance is lost, and (4) late bud break (Daubeney, 1996). It has been proven difficult to combine cold hardiness with early flowering and fruiting (Jennings *et al.*, 1989).

While blackberries are less winter hardy than raspberries, there is still a wide range in the hardiness of cultivars and species (Hall, 1990). The European cultivar "Merton Thornless" is one of the least tolerant ones, and its use as a source of spinelessness led to reductions in hardiness in Europe and North America (Jennings *et al.*, 1989). The largest gain in hardiness has come from breeding cultivars with trailing canes that are covered by snow.

Raspberries grown in the colder regions can also be limited by fluctuating spring and fall temperatures, and low temperatures during fruiting. There is considerable variability among raspberry genotypes in their ability to set high proportions of their drupelets under cool conditions. In general, the raspberry cultivars developed in the United Kingdom are better adapted to cool temperatures than those developed in the Pacific Northwest, with some exceptions. The northwestern cultivar "Meeker" has been shown to have good drupelet set at both locations (Dale and Daubeney, 1985).

Heat and drought are limiting in southern Europe, southeastern North America, and much of the southern hemisphere. In many of these

areas, cultivars with a low chilling requirement are also needed, as hot summer temperatures are often associated with limited chilling hours. Considerable variability has also been found among raspberry and blackberry cultivars for adaptation to high summer temperatures. In most cases, those cultivars with high temperature tolerance also have a reduced chilling requirement, and most of the heat tolerant genotypes are also drought tolerant. The wild Asiatic raspberry species have been most widely used as sources of high temperature tolerance and a low chilling requirement, although genes regulating a low chilling requirement have been found in cool weather adapted *R. ideaus* (Rodriquez and Avitia, 1989).

The most desired cultivars are erect and sparsely spined, with adequate but not excessive cane numbers and cane heights (Jennings *et al.*, 1989). Spines are more prominent in blackberries than raspberries, and thus have received a higher priority in their breeding. Most raspberry cultivars are not completely spine free, but spineless ones do exist and many at least have reduced numbers on the basal portions of canes. There is an apparent association between spinelessness and susceptibility to winter injury that requires large population sizes to identify recombinants (Moore, 1984). Dominant genes for spinelessness have been found, but to date most of the genes used to produce spineless cultivars are recessive (Daubeney, 1996).

The critical traits associated with high fruit quality in raspberry and blackberry are flavor, soluble solids, acidity, color, texture, skin strength, fruit size, seed size, ability to maintain integrity, ease of removal, nutritional content, and ripening season. Raspberries with an intense red color without any blue are considered best for the fresh market, yogurt, and pie fillings (Jennings *et al.*, 1989). Blackberries must retain their black color and not turn red in storage and after freezing. Seeds are more of a problem in blackberries than raspberries, but in general, low numbers of small seeds are best. Considerable genetic variability exists for all of these fruit characteristics among cultivars and species, although few studies have been performed to determine their genetics. Barritt (1982) found very high heritability for fruit firmness in a diverse breeding population of raspberries containing genotypes from the Pacific

Northwest and the United Kingdom. Single genes have been identified for fruit color, fruit size, and crumbly fruit (Daubeney, 1996).

Connor *et al.* (2005a) estimated narrow-sense heritabilities for antioxidant capacity (AA), total phenolic content (TPH), and fruit weight from progeny of a factorial mating design of seven female and six male red raspberry genotypes. Heritability estimates were all high, at 0.54, 0.48, and 0.77 for AA, TPH, and fruit weight, respectively. In further work evaluating individual ACY content with total ACY content and antioxidant capacity in the same families, Connor *et al.* (2005b) found high values of h^2 for individual ACYs (0.54–0.90), but ACY content and profile information were “inefficient proxies and predictors of AA in red raspberry fruit”. The inclusion of a pigment-deficient *R. parvifolius* × *R. ideaus* hybrid resulted in significant female and male contributions to variation, but its removal from the analysis made female × male interaction negligible.

1.5.3 Strawberries

Several soil pathogens damage strawberry roots, resulting in vigor declines and death in severe cases. Two very common problems across the world are red stele or red core caused by *Phytophthora fragariae* Hickman and verticillium wilt caused by *Verticillium albo-atrum* Reinke & Berth. and *V. dahlia*. Black root rot is also widespread and is caused by a complex of organisms including *Pythium*, *Rhizoctonia*, and the root lesion nematode (*Pratylenchus penetrans* Cobb). *Fusarium* wilt or *Fusarium* yellows (*Fusarium oxysporium* Schl. f. sp. *fragariae* Winks and Williams) is of major importance in Japan, Korea, and Australia. Resistant and/or tolerant genotypes have been found for all four of these major soil pathogens, but for all of them, the genetics are complex (Hancock, 1999).

Fumigation has been widely employed to control these soil pathogens, but the impending ban on methyl bromide (MB) fumigation has stimulated increased interest in developing resistant cultivars. The identification of a transgene that conferred broad resistance to a number of soil pathogens would be particularly desirable. Without fumigation, cultivars yield 50% less fruit on average. Screens of the California breeding

population on fumigated and nonfumigated soil have uncovered little general resistance to the total array of soil pathogens normally found in strawberry soils (Larson and Shaw, 1995a, b), although a screen of eastern breeding material did uncover some tolerant individuals (Patrica and Hancock, 2005).

Three foliar diseases are very widespread and routinely cause serious damage including, leaf blight (*Phomopsis obscurans* (Ell. and Ev.) Sutton), Ramularia leaf spot (*Mycosphaerella fragariae* (Tul.) Lindau), and leaf scorch (*Diplocarpon earliana* (Ell. & Everh.) Wolf). *Alternaria* leaf spot or black leaf spot (*Alternaria alternaria* (FR.) Keissler) causes serious damage in Europe, New Zealand, and Korea. Powdery mildew (*Sphaerotheca macularis* (Wallr. Ex Fr.) Jaesz) is also found across most of the strawberry range, although it rarely does economic damage. Angular leaf spot, *Xanthomonas fragariae* Kennedy and King, is a rapidly growing problem in strawberries all across the world (Maas *et al.*, 1995). For most of these diseases, only quantitative resistance has been found with moderate to high levels of heritability. Only black leaf spot resistance has been reported to be controlled at a single locus (Yamamoto *et al.*, 1985).

Anthrachnose is a common problem in strawberries, causing a wide array of symptoms including fruit rot, crown rot, and lesions of the stolons, petioles, and leaves. Anthracnose diseases of strawberry are caused by *Colletotrichum fragariae* A.N. Brooks, *C. acutatum* J.H. Simmonds, and *C. gloeosporioides* (Penz.) Penz. & Sacc. in Penz. *Colletotrichum acutatum* is the primary pathogen causing crown rot in Europe (Denoyes-Rothan and Baudry, 1995), while *C. fragariae* is the most common cause of crown rot in the southeastern United States. Sources of resistance to anthracnose fruit and crown rots exist in strawberry; however, the genetic factors conditioning host resistance to crown and fruit infection differ and only a few genotypes are resistant to both fruit and plant. Strong environmental × genotype interactions affect the expression of resistance, and multiple isolates of *C. acutatum*, *C. gloeosporioides*, and *C. fragariae*, vary in pathogenicity to *Fragaria* genotypes (Smith and Black, 1987).

Phytophthora cactorum (Leb. & Cohn) Schroet also causes widespread incidences of severe crown (Cactorum crown rot) and fruit rots (leather rot),

particularly in warm climates. Other important fungal fruit rots are as follows: (1) botrytis fruit rot or gray mold (*Botrytis cinerea* Pers. ex. Fr.), which is a worldwide problem, (2) mucor fruit rot (*Mucor mucedo* L. ex Fries), sometimes important in the United States and United Kingdom, (3) rhizopus leak (*Rhizopus* spp.) a particular problem in the United Kingdom but worldwide in scope, (4) tan-brown rot, (*Discohainesia oenotherae* (Cook & Ellis)), a major problem in humid strawberry regions, (5) *Phomopsis obscurans* (Ellis & Everh.) Sutton in Florida, and (6) septoria hard rot (*Septoria fragariae*) rarely a problem in the United States but common in Europe and Australia. Moderate to high levels of heritability have been found to gray mold and leather rot.

Strawberries across their range are hosts to numerous viruses and phytoplasma. Among the most important are the aphid-borne viruses involved in the yellows complex (mottle, mild yellow-edge, crinkle, and vein banding viruses) and the nematode-borne viruses (raspberry ringspot virus, tomato black ring, strawberry latent ringspot virus, and arabis mosaic virus) (Maas, 1998). There are also two important phytoplasma diseases spread by leaf hoppers, Aster yellows that are caused by a cultivar of species and green petal or clover phyllody. Resistance has been identified to the regional virus complexes found in the Pacific Northwest, but no formal genetic analysis has been performed.

The nematodes causing the most widespread problems include the northern root-knot nematode (*Meloidogyne hapla* Chitwood), root lesion nematode, and the needle nematode (*Longidorus elongatus* Dorylaimida). Resistance has been described for all these pests, although no genetic studies have been conducted.

Two aphids are widespread that damage strawberries, the strawberry root aphid, *Aphis forbesi*, and the strawberry aphid *Chactosiphon fragaefolii* (Corherell). The strawberry aphid is found all across the range of cultivation, while the strawberry root aphid is restricted to east of the Rockies in the United States. The latter is most important as a vector of virus disease. Resistant genotypes have been identified for the strawberry aphid, and resistance has been shown to be regulated by more than one locus with partial dominance and additive action (Hancock, 1999). Other important strawberry pests are plant

bugs (*Lygus* spp.), root weevils (*Otiorhynchus* spp.), strawberry weevil (*Anthonomus signatus* Say), two-spotted spider mite (*Tetranychus urticae* Koch.), and the cyclamen mite (*Steneotarsonemus pallidus* (Banks)). Moderate levels of resistance have been identified to two-spotted spider mite, strawberry aphid, and black vine weevil.

Excess salt from irrigation water is a major production problem in many arid agricultural regions. Water containing more than 100 ppm sodium or chloride ions results in enough salt accumulation to cause yield loss without visible plant injury (Brown and Voth, 1956). Some cultivars have been shown to be more "salt tolerant" than others, but no formal genetic studies have been made.

Strawberries generally bloom in early spring, when the chance of frost is relatively high in many strawberry production regions. Flower buds, open flowers, and young fruit are all injured by frost. Pistillate parts are most sensitive to damage; however, some damage is likely to all parts if temperatures fall to -2°C (Darrow, 1966). Differences in bloom tolerance to frost have been described in the older literature (Ourecky and Reich, 1976); however, all of our modern cultivars have flowers that are highly sensitive to frost.

Winter freezing injury to the strawberry crown and inflorescence buds is a serious limitation to strawberry production throughout the upper half of the Northern Hemisphere. Nonacclimated strawberry plants are usually killed when the crown temperature remains at -3°C for more than 1 or 2 h (Scott and Lawrence, 1975). Acclimated strawberry plants can survive crown temperatures of -12°C to -15°C , although injury such as decreased vigor is visible at higher temperatures. The greatest amount of damage occurs in the late winter to early spring when temperatures rapidly rise and then drop again. Early breeders dramatically improved the winter hardiness of northern cultivars using quantitative variability, but little improvement in this trait has been made in the last few decades.

Several factors can restrict consumer acceptance of strawberry fruit including size, firmness, flavor, nutrition, and color. There is considerable variability for these traits available in most breeding populations, although inheritance is generally polysomic. Size of fruit is inherited quantitatively, with 6 to 8 allelic pairs controlling

fruit expansion (Hancock, 1999). Flesh firmness and skin toughness are often correlated positively and are generally inherited quantitatively. Skin and flesh color have been shown to be largely under the control of additive variation, although a few genes appear to have much larger effects than others. Internal and external colors are probably regulated by separate sets of genes as correlations between these two parameters are small.

Soluble solids and acidity are controlled with varying levels of additive and dominance control (Shaw *et al.*, 1987; Shaw, 1988). Shaw (1988) found little difference in the soluble solids and total sugars in his breeding population, although he did observe significant genotypic variation in sucrose, glucose, fructose, and acidity levels. Wenzel (1980) found a negative association between soluble solids concentration and yield. Vitamin C content has also been shown to be polygenic, with some parents displaying partial dominance for high levels and some progeny having higher levels than their parents (Hancock *et al.*, 1996). Several studies have described variation in the flavor of progeny families suggesting additive quantitative control (Darrow, 1966), although few formal genetic studies on this character have been conducted. Zubov and Stankevich (1982) found significant seedling variation in fruit consistency, ACY content and vitamin C, but not flavor.

2. DEVELOPMENT OF TRANSGENIC BERRY CROPS

2.1 Donor Genes

2.1.1 Blueberry and cranberry

Two groups have reported on the transformation of blueberry (Graham *et al.*, 1996; Song and Sink, 2004). The screenable reporter *gusA* driven by either the cauliflower mosaic virus (CaMV) 35S or a chimeric super promoter (Aocs)₃AmasPmas (Ni *et al.*, 1995) and terminated by T-nos was transformed into blueberry cultivars using *nptII* as the selectable marker. The *bar*, driven by P-nos and terminated by the gene 7 poly(A) signals (Becker *et al.*, 1992) was also transformed into blueberry plants after selection with glufosinate ammonium. High-level tolerance to glufosinate-herbicide Rely, 750–3000 mg l⁻¹ glufosinate ammonium, was

observed in the *bar*-expressing, greenhouse plants (Song *et al.*, 2007). Field trials showed little or no damage to plants from four independent transgenic events after application of a workable concentration of glufosinate ammonium, 750 mg l⁻¹, for weed control (Song *et al.*, 2007).

Successful transformation of cranberry has only been reported by a group from the University of Wisconsin-Madison. In their initial work, a vector containing the *gusA*, *nptII*, and *Bt* (*Bacillus thuringiensis* Subsp. *Kurstaki* crystal protein) was used to optimize transformation protocols for the cultivar Stevens (Serres *et al.*, 1992; Serres *et al.*, 1997). Both *gusA* and *Bt* were controlled by the CaMV 35S promoter, while *nptII* had a nopaline synthase promoter (P-nos). All three genes were terminated by the nopaline synthase polyadenylation region. In later work, they transformed two genes, *nptII* and *bar*, into “Pilgrim” to obtain herbicide-resistant plants (Zeldin *et al.*, 2002). The *bar* gene was driven by the CaMV 35S promoter and terminated by the soybean small subunit gene polyadenylation signal region (T-nos).

The genes encoding the cold-responsive proteins known as dehydrins have been cloned in blueberry. Muthalif and Rowland (1994a, b) originally examined changes in protein levels in the floral buds of the cold-tolerant, northern highbush “Bluecrop” and the cold-sensitive rabbiteye “Tifblue.” They found that three proteins of 65, 60, and 14 kDa increased in both cultivars in response to cold and became the predominant proteins. The highest levels of the dehydrins were found in “Bluecrop.” This correlation has held up across a number of other cultivars with varying levels of cold tolerance (Arora *et al.*, 1997; Panta *et al.*, 2001). A 2.0 kb blueberry complementary DNA (cDNA) was identified that encodes the 60 kDa dehydrin (*bbdhn1*) (Levi *et al.*, 1999). This clone was used to probe cold-hardened floral buds of “Bluecrop” and another five dehydrins were identified (*bbdhn2*–*bbdhn5*) (Rowland *et al.*, 2004).

A large expressed sequence tag (EST) library of highbush blueberry has been generated in the laboratory of L. J. Rowland at the USDA-ARS Fruit Laboratory at Beltsville, Maryland. Through traditional molecular genetic and genomic approaches, she and her collaborators have identified and isolated several genes associated

with cold hardiness including several members of the dehydrin gene family (Muthalif and Rowland, 1994a, b; Dhanaraj *et al.*, 2003, 2005). They have also conducted gene expression studies under field and cold room conditions using cDNA microarrays (Dhanaraj *et al.*, 2006a, b).

2.1.2 Cane fruit

Regeneration and transformation systems have been developed for blackberries and raspberries utilizing leaves, cotyledons, and internodal stem segments (Hassam *et al.*, 1993; Mathews *et al.*, 1995a; Graham *et al.*, 1997a; Kokko and Karenlampi, 1998; Meng *et al.*, 2004). Most of the *Rubus* transformations have been with marker genes *GUS*, *NPTII*, and *CSR* (chlorsulfuron herbicide resistance).

Mathews *et al.* (1995b) transformed “Canby”, “Chilliwick”, and “Meeker” red raspberries with the gene for S-adenosylmethionine (SAMase), as a potential strategy to delay fruit decay. Leaf and petiole explants were inoculated with *Agrobacterium* strain EHA 105 carrying the binary vectors pAG1452 or pAG1552 encoding SAMase under control of the wound and fruit-specific E4 promoter. Petiole explants produced the highest rates of transformation, and more transformants were recovered using hygromycin phosphotransferase (HPT) as the selective agent rather than neomycin phosphotransferase (NPTII). They reported on establishment of the transformants in soil, but have not published information on levels of resistance to decay.

There have been two attempts to generate resistance to RBDV using *Agrobacterium*-mediated transformation. Jones *et al.* (1998) isolated the coat protein gene (*cp*) from a resistance-breaking strain of RBDV and transformed plants with it in the sense and antisense orientation. Some of their transformants were partially resistant. Taylor and Martin (1999) sequenced the *cp* gene, mutations of the movement protein and nontranslatable RNA of RBDV, and transformed “Meeker” red raspberry with each of these constructs (Martin and Mathews, 2001). A small number of bramble genes have been identified and sequenced. Twenty genes associated with fruit ripening were identified by Jones *et al.* (1999) in the red raspberry “Glen Clova.” Most

of these genes were associated with cell wall hydrolysis and ethylene biosynthesis. Iannetta *et al.* (2000) cloned two putative endo- β -1,4 glucanase genes (*RI-EGL1* and 2) from ripe receptacle messenger RNA (mRNA). The expression of these genes were limited to ripe fruit receptacles, and the application of 1-methylcyclopropene (1-MCP) to green fruit indicated that ethylene accelerates raspberry abscission and increases EGase activity.

Ramanathan *et al.* (1997) cloned two genes for polygalacturonase-inhibiting protein (*PGIP1* and *PGIP2*) that could play a role in gray mold resistance. Plant polygalacturonase-inhibiting proteins (PGIPs) inhibit fungal endopolygalacturonases, which are released by fungi to degrade plant cell walls. Activity levels of *PGIP* were found to decline during floral and fruit development, but expression of *PGIP* was stable throughout development from closed flower to ripe fruit.

2.1.3 Strawberry

Two types of herbicide resistance have been engineered into strawberry through *Agrobacterium*-mediated transformation. The phosphinothricin acetyl transferase gene (*PAT*) was incorporated into the “Selekta” strawberry using *Agrobacterium*-mediated gene transfer (Duplessis *et al.*, 1995, 1997). Putatively transformed shoots were rooted and established in the greenhouse and most transgenic plants were found to be resistant to the herbicide glufosinate-ammonium (Ignite). The *CP4.EPSP* synthase gene, which confers resistance to glyphosate (Roundup®) was introduced into “Camarosa” (Morgan *et al.*, 2002), and when 73 independent transformations were sprayed with Roundup® in the nursery, a range of responses were noted from complete resistance to death. Expression levels of the *CP4.EPSPS* gene was strongly correlated with phenotype. The best lines were subsequently tested in the field and appeared to produce good quality fruit.

To provide insect resistance, the cowpea protease trypsin inhibitor gene (*CpTi*) (Agricultural Genetics Company, Cambridge, England) was incorporated into strawberry via *Agrobacterium*-mediated transformation using the *NPTII* marker (Graham *et al.*, 1995, 1997b, 2002). The insertion of *CpTi* into strawberry cultivars “Melody”

and “Symphony” was found to reduce vine weevil (*Otiorhynchus sulcatus*) damage in both greenhouse and field trials. The transgenic lines showed increased root growth, less larval feeding, and fewer pupae. In other work, strawberries transformed with the lectin *Galanthus nivalis* agglutinin (GNA), did not show any significant reduction in weevil feeding (Graham, 2005).

Enhanced resistance to *Verticillium dahliae* was observed in transgenic “Joliette” strawberry plants expressing a *Lycopersicon chilense* chitinase gene (*pcht28*) under the control of the CaMV 35S promoter (Chalavi *et al.*, 2003). A stipule regeneration system was used with *Agrobacterium*-mediated gene transfer. Constitutive expression of the chitinase gene was demonstrated by Northern analysis, and in growth chamber studies, transgenic strawberry plants had significantly higher resistance than controls, based on rates of crown infection and leaf wilting symptoms.

A gene encoding a PGIP has been cloned that shows developmental regulation and pathogen-induced expression in strawberry and likely plays a role in defense against fruit rots (Mehli *et al.*, 2004, 2005; Schaart *et al.*, 2005). After inoculation with *Botrytis cinerea*, fruit of five cultivars (“Elsanta”, “Korona”, “Polka”, “Senga Sengana”, and “Tenira”) showed a significant induction in PGIP expression and the most resistant one, “Polka”, had the highest constitutive expression. Work is ongoing to produce transgenic strawberries that overexpress PGIP sequences and screen them for resistance to *B. cinerea*.

The antisense of strawberry pectate lyase was incorporated into “Chandler” strawberry under control of the 35S promoter to increase fruit firmness (Jiménez-Bermúdez *et al.*, 2002). At full ripening, no differences in color, shape, and weight were noted between the transgenic and control plants, but the transgenics were significantly firmer. Pectase lyase activity was 30% lower in ripe transgenic fruit than the control. In another study, Jiménez-Bermúdez *et al.* (2002) found that expression of an antisense sequence of a strawberry pectate lyase gene reduced ascorbic acid content, presumably through reduced pectin solubilization in cell walls of transgenic plants.

Two endo- β -1,4-glucanase (EG) genes, *cell*, and *cel2*, have been isolated from strawberry that are closely related to tomato genes influencing softening. *Cell* is expressed specifically in ripening

fruit (Manning, 1998), while *cel2* mRNA is found primarily in young vegetative tissues and early green fruit (Trainotti *et al.*, 1999). *Cell* has been cloned into strawberry in the antisense orientation via *Agrobacterium*-mediated transformation using the plant binary vector pBINPLUS (Woolley *et al.*, 2001). In the transgenic strawberries, mRNA was strongly suppressed in ripe fruit; however, EG activity and firmness were not affected. The incorporation of *cell* had no effect on the transcription of *cel2*.

The S-adenosylmethionine hydrolase gene (*SAMase*) has been incorporated into strawberry, which controls ethylene biosynthesis and presumably effect fruit softening (Mathews *et al.*, 1995b). Strawberries are not climacteric fruit, but do have a limited response to ethylene and it is possible that reductions in ethylene biosynthesis during the post harvest period could slow down softening.

De la Fuente *et al.* (2006) has cloned *FaGAST* from strawberry, which encodes a small protein with 12 cysteine residues conserved in the C-terminal region that is similar to a group of proteins in other plant species that regulate cell division and elongation. Expression of *FaGAST* in transgenic *F. vesca* under the control of CaMV 35S resulted in delayed fruit growth, reduced fruit size, late flowering, and low sensitivity to gibberelin. Apparently, *FaGAST* plays a role in arresting fruit elongation during strawberry fruit ripening.

A number of recent molecular studies have searched for the genes in strawberry that are involved in cell wall modification during ripening and, therefore, influence fruit firmness. Harrison *et al.* (2001) identified and characterized a number of expansin genes (*FaExp2* to *FaExp7*), which likely induce cell wall extension *in vitro*. Messenger RNAs from most of these were present in leaves, roots, and fruit, except for *FaExp5*, which showed fruit-specific expression. Castillejo *et al.* (2004) isolated four pectin esterases from strawberry (*FaPE1* to *FaPE4*). *FaPE1* was specifically expressed in fruit and was upregulated by auxin treatment in green fruit and downregulated by exogenous applied ethylene in ripe and senescing fruits. The repression of *FaPE1* may be involved in textural changes during fruit senescence. Blando-Portales *et al.* (2004) identified a fruit-specific gene encoding for a HyPRP protein involved in the anchoring of polyphenols to cell membranes. Salentijn *et al.* (2003) found the expression of

two genes associated with lignin metabolism (cinnamoyl CoA reductase and cinnamyl alcohol dehydrogenase) to vary dramatically between soft fruited ("Gorella") and firm-fruited ("Holiday") cultivars.

Three full-length cDNAs encoding β -galactosidases (*Fa β gal1*, *Fa β gal2*, and *Fa β gal3*) were isolated from a library representing red fruit transcripts by Trainotti *et al.* (2001). Two of the genes had a C-terminus domain that was structurally related to known animal peptides with sugar-binding ability. Galactose is released during the dismantling of cell walls and the galactosidases are thought to play an important role in the mobilization of galactose. In a study of salt-extractable proteins from the cell walls of immature and ripe strawberry, Iannetta *et al.* (2004) identified seven abundant polypeptides, two of which were thought to be important determinants in the regulation of the sugar:acid balance (mitochondrial malate dehydrogenase and mitochondrial citrate synthase).

DNA microarrays have been utilized to identify and clone genes associated with strawberry flavor and aroma. Aharoni *et al.* (2000) identified a novel strawberry alcohol acyltransferase (SAAT) in *F. \times ananassa* cultivar Elsanta that is critical in flavor biogenesis in ripening fruit. This gene combines acyl-CoA and alcohol to generate the esters, the most important class of volatile compounds in fruit. Aharoni *et al.* (2004) also cloned the gene, *F. ananassa Nerolidol Synthase 1* (*FaNES1*), which was found in all three octoploid species, but not in *F. vesca* and *F. moschata*. It generates linalool and nerolidol when supplied by geranyl diphosphate or farnesyl diphosphate. They also found *F. vesca* to carry an insertion mutation in a terpene synthase gene that differs from the one in the cultivated strawberry (*F. ananassa Pinene Synthase*). This insertion limited its expression and further altered aroma by reducing quantities of pinene and myrcene.

A number of other genes have been characterized that are highly expressed during fruit ripening and maturation. Manning (1998) generated a cDNA library from messenger RNA isolated from ripe fruit, and identified a number of genes encoding enzymes of phenylpropanoid metabolism, and genes for cellulase, expansins, cysteine proteinase, and acyl carrier protein. Three mRNAs with fruit-specific, ripening-enhanced

expression have also been identified in ripening fruit using polymerase chain reaction (PCR) differential display (Wilkinson *et al.*, 1995). When sequenced, they had high homology with known proteins including: (1) an annexin, which may play a role in membrane function and cell wall structure, (2) chalcone synthase (CHS), which is a key enzymatic step in flavonoid biosynthesis, and (3) a ribosomal protein, most likely a 40S subunit. In addition, a gene (*njjs4*) has been identified, which is associated with the process of seed maturation and fruit ripening, and is related to the class-I LMW heat-shock-protein-like genes (Medina-Escobar *et al.*, 1998). Two auxin-induced and one auxin-repressed mRNAs from unknown genes have been cloned from receptacles of immature green fruit (Reddy *et al.*, 1990; Reddy and Poovaiah, 1990). Yubero-Serrano *et al.* (2003) identified a gene encoding a lipid transfer protein (*Fxaltp*) in strawberry fruit that responds to ABA, wounding, and cold stress. Aharoni *et al.* (2001) cloned the transcription factor *FaMYB1* from ripening fruit, which plays a key role in the biosynthesis of ACYs and flavonols.

Hoffman *et al.* (2006) used RNA interference (RNAi)-induced silencing to reduce activity of CHS in strawberry fruits (Figure 1). They used a construct (*ihpRNA*) containing the partial sense and corresponding antisense sequences of CHS separated by an intron (from a strawberry quinone oxidoreductase gene). An *Agrobacterium* suspension containing the gene was injected into 14-day-old fruit still attached to the plant. Almost white fruit were produced when the injection was repeated 3 days in a row.

DNA microarrays have also been used to profile cosmic patterns of gene expression during ripening. Aharoni and O'Connell (2002) found 441 transcripts to differ significantly between the achene and receptacle tissues. The most common transcripts found in achenes were those for signal and regulation cascades associated with achene maturation and stress tolerance. Representatives included phosphatases, protein kinases, 14-3-3 proteins, and transcription factors. Several genes were identified in the receptacle that encode proteins related to stress, the cell wall, DNA/RNA protein, and primary metabolism.

An NADPH-dependent D-galacturonic acid reductase gene (*GalUR*) was isolated and characterized from strawberry to determine its role in

Figure 1 Silenced phenotypes of the *FaCHS-ihpRNA* transformed strawberries. (a) A chimeric phenotype where a solution of *Agrobacterium* containing the *ihpRNA* was injected. (b) An almost white fruit produced when the injection was repeated three times. (c) Control plants. (d, e, and f) cross sections of two chimeric fruit and a control [Reproduced from Hoffman *et al.*, 2006. © Blackwell Publishing]

vitamin C content (Angius *et al.*, 2003). Expression of *GalUR* correlated closely with ascorbic acid levels during strawberry fruit ripening and *GalUR* protein levels were found to be associated with ascorbic acid content in four species of *Fragaria* (*F. × ananassa*, *F. chiloensis*, *F. virginiana*, and *F. moschata*). The gene was not engineered into strawberry, but overexpression of *GalUR* in *Arabidopsis* enhanced vitamin C content two to threefold.

The acidic dehydrin WCOR410 from wheat was transferred to strawberry in an attempt to improve freezing tolerance (Houde *et al.*, 2004). The WCOR410 protein has been associated with the plasma membrane in wheat and its levels have been correlated with freezing tolerance. After acclimation, transgenic strawberry leaves had a 5°C improvement in freezing tolerance compared to controls. However, there was not a difference in the freezing tolerance of nonacclimated transgenics and controls, suggesting that another factor induces its expression during cold acclimation. Transgenic strawberries have also been developed that expressed antifreeze protein

gene (*AFP*) isolated from white flounder (Firsov and Dolgov, 1998), but no freezing trials were conducted.

In an earlier attempt to increase the freezing tolerance of strawberries, the transcription factor *CBF1* from *Arabidopsis* was overexpressed in the strawberry “Honeoye” (Owens *et al.*, 2002). The *CBF* genes are part of a family of cold- and drought-inducible transcription factors that bind to promoters containing a C-repeat/dehydration responsive element (CRT/DRE). This element is found in many cold-induced plant genes. *Agrobacterium*-mediated transformation with a CaMV 35S-*CBF1* construct was utilized to produce transgenic strawberries. The freezing tolerance of strawberry leaf discs from nonacclimated plants was significantly increased by 3–5°C. However, the freezing tolerance of floral tissue was not, despite expression of the *CBF1* transgene in receptacles at levels similar to developing leaves. A putative ortholog (*F. × ananassa CBF1* (*FaCBF1*)) was identified with 48% amino acid identity to *CBF1* from *Arabidopsis*.

To elucidate the molecular basis of cold acclimation in strawberry, Ndong *et al.* (1997) used differential screening to identify genes associated with low temperature acclimation. They identified three transcripts, *Fcor1-3* (*Fragaria cold-regulated 1-3*), whose levels changed dramatically after cold acclimation. Transcript accumulation for *Fcor3* was the most closely correlated with freezing tolerance, suggesting it may be a useful marker for this trait. *Fcor3* encodes a polypeptide that shows high identity with PSI polypeptides from spinach and barley.

The late embryogenesis abundant protein gene (*LEA3*) from barley (*Hordeum vulgare*) was used to transform the “Toyonaka” strawberry (Wang *et al.*, 2004) in hope of increasing the resistance of strawberry to salt stress. Calli from anthers were transformed by particle bombardment with plasmid pBY520. *In vitro* plants of transgenic strawberry had significantly less wilting than controls under 50 mmol l⁻¹ (19% vs. 62%) and 100 mmol l⁻¹ NaCl (43% vs. 96%).

Mezzetti *et al.* (2004) developed transgenic strawberries and raspberries carrying the *defH9-iaaM* auxin-synthesizing construct, composed of the regulatory region of the *DefH9* gene from snapdragon and the *iaaM* coding region from *Pseudomonas syringae*. The *defH9-iaaM*

gene was found to promote parthenocarpy in emasculated flowers of both strawberry and raspberry, and to increase fruit size, weight, and yield.

The FBP7 promoter (floral binding protein7) from petunia was found to be active in floral and fruit tissues of strawberry, using the β -glucuronidase gene as a reporter (Schaart *et al.*, 2002). β -glucuronidase (GUS) activity was found in floral and fruit tissues, but not vegetative ones, although *gus*-derived mRNAs were found in roots and petioles. The 35S promoter was found to be sixfold stronger than the FBP7 promoter.

Agius *et al.* (2005) used a transient expression system to conduct a functional analysis of homologous and heterologous promoters in strawberry fruit. The CaMV 35S promoter was fused to the *LUC* gene to optimize the transient assay. The GalUR promoter from strawberry was found to be active in fruit and under light regulation. Slight activity in fruit was found for the pepper fibrillin promoter, but not for the tomato polygalacturonase promoter.

A MADS box gene from strawberry, *STAG1*, has been cloned and characterized in transgenic plants (Rosin *et al.*, 2003). *STAG1* shares 68–91% sequence homology with *AGAMOUS* from numerous plant species. Analysis of the expression patterns of a *GUS* marker gene driven by the *STAG1* promoter revealed that *STAG1* was active in stamens, receptacles, petals, central pith, and vascular cells during floral development and achenes, pith, and cortical cells during fruit ripening.

Three major EST libraries of have been generated as genomic resources in strawberry. A cDNA library of over 1800 ESTs has been produced from whole plants treated with salicylic acid by Folta *et al.* (2005). A cDNA library of *F. vesca* with over 2500 ESTs has also been being constructed by Davis (2005). These efforts are part of a major Rosaceae Genomics Project centered at the Clemson University (http://www.mainlab.clemson.edu/gdr/about_gdr.shtml). Batley *et al.* (2005) have generated over 23 600 ESTs from a range of tissues, developmental stages, and experimental conditions, and identified 11 690 single nucleotide polymorphisms (SNPs) and 4200 SSRs for mapping. Their focus is on traits such as day neutrality and the fruit characteristics of firmness, flavor, taste, aroma, and color.

2.2 Transformation Methods Employed

2.2.1 Blueberry and cranberry transformation

2.2.1.1 Blueberry

Agrobacterium tumefaciens-mediated transformation is the only published approach that has yielded transgenic blueberry plants. Graham *et al.* (1996) described the transformation and regeneration of the “half high” blueberry “North Country” (*V. corymbosum* \times *V. angustifolium*), using *A. tumefaciens* strain LBA4404 (Hoekema *et al.*, 1983) with a binary vector carrying an intron-containing *GUS* marker gene (Vancanneyt *et al.*, 1990). They found “North Country” to be hypersensitive to kanamycin and ticarcillin, and as a result, they did not use antibiotic selection. The regenerates were shown to be GUS-positive, but a Southern analysis was not performed to confirm transformation.

Song and Sink (2004) generated Southern blot-confirmed transgenic plants of highbush blueberry of four cultivars: “Aurora”, “Bluecrop”, “Brigitta”, and “Legacy” (Figure 2). Two selectable marker genes, *nptII* and *bar*, were used to produce the transgenic plants (Song and Sink, 2004; Song *et al.*, 2007). Their optimized transformation and selection protocols yielded transgenic plants at frequencies of 15.3% for “Aurora”, 5.0% for “Bluecrop”, 10.0% for “Brigitta”, and 5.6% for “Legacy”. Residual bacteria were successfully controlled using cefotaxime. The effect of glufosinate-ammonium (GS) on regeneration was also investigated and the combination of 0.1 mg l⁻¹ GS with 250 mg l⁻¹ timentin yielded effective shoot inhibition without leading to rapid death of explants. The protocol was then used to produce herbicide-resistant transgenic plants of “Legacy” (Song *et al.*, 2007). A detailed step-by-step description of the transformation procedure can be found in Song and Sink (2006).

Overall, *in vitro*-derived leaves have been found to be the most useful explant source in blueberry regeneration (Billings *et al.*, 1988; Callow *et al.*, 1989; Rowland and Ogden, 1992). Nickerson (1978) first reported low-bush blueberry regeneration from hypocotyl or cotyledon sections; however, shoot regeneration from seedling explants is not preferable since

Figure 2 Transformation, selection, and regeneration of transgenic blueberry plants of the cv. Aurora. (A) Nontransformed leaf explants (a) on RM, (b) on RM containing 10 mg l^{-1} Km and 250 mg l^{-1} Cx, *Bar* = 1 mm. (B) Production of Km-resistant buds and shoots from surface (a) or wounded positions (b) of leaf explants, *Bar* = 1 mm. (C) Formation of Km-resistant shoot clusters from different positions of leaf explants, *Bar* = 1 mm. (D) Elongation of GUS-positive shoots on RM (a) or stock culture medium (b) containing 10 mg l^{-1} Km and 250 mg l^{-1} Cx, *Bar* = 1 mm (D-a), 1 cm (D-b) [Reproduced from Song and Sink, 2004]

blueberries are asexually propagated. Several medium and hormone combinations have been used to regenerate shoots. The cytokinin 6-(γ,γ -dimethylallylamino)-purine (2ip) was first examined to promote shoot regeneration from leaf explants, since it was effective for blueberry micropropagation. On woody plant medium (Lloyd and McCown, 1980) supplemented with $15 \mu\text{M}$ 2ip, 70–100% of leaf explants regenerated shoots from leaf explants of “Berkeley” and “Bluehaven”, and the mean number of shoots per regenerating leaf was about 7 (Billings *et al.*, 1988). On half strength MS medium +5 to $25 \mu\text{M}$ 2ip, adventitious shoots were produced on leaf explants of “Bluecrop”, “Bluejay”, and “Jersey”. Rowland and Ogden (1992) found that zeatin riboside was more effective than either of the cytokinins, 2ip and zeatin, in promoting shoot regeneration for leaf explants of “Sunrise”; whereas, “Bluecrop” and “Duke” produced no shoots on any of the media tested.

Hammerschlag’s group improved adventitious shoot organogenesis from leaf explants of five highbush cvs. using either thidiazuron (TDZ) at 1 or $5 \mu\text{M}$, or zeatin riboside at $20 \mu\text{M}$

(Cao and Hammerschlag, 2000; Cao *et al.*, 2002); a two-step pretreatment in liquid medium, including 4 days using $5 \mu\text{M}$ TDZ + $2.6 \mu\text{M}$ naphthaleneacetic acid (NAA) and 3 days using $7 \mu\text{M}$ zeatin riboside + $2.6 \mu\text{M}$ NAA, enhanced shoot regeneration of “Bluecrop” (Cao *et al.*, 2002). Shoot regeneration of six cultivars was evaluated after seven treatments on different media.

Song and Sink (2004) found that adventitious shoot regeneration occurred for all cultivars at high frequencies (86.7–100%), but the optimum treatment(s) varied among cultivars. TDZ and NAA were effective in promoting adventitious shoot formation for all of the cultivars in terms of the number of shoots per explant. Those cultivars that readily produced shoots by elongation of the buds on stem pieces placed horizontal on proliferation medium also regenerated shoots readily from leaf explants (Song and Sink, 2004).

Two studies have examined the factors influencing the early stages of transformation. Cao *et al.* (1998) used transient *gusA* expression to test the effects of *Agrobacterium tumefaciens*

strain, cocultivation, explant age, genotype, and sucrose concentration in the medium. They used 10 highbush cultivars and strains LBA4404 and EHA105, containing the binary vector p35SGUSint. LBA4404 was found to be much less virulent than EHA105, and 4 days of cocultivation with EHA105 yielded 50-fold more GUS-expressing zones than 2 days, with genotype and explant age also being important factors. Song and Sink (2004) found leaf explants to be susceptible to three *A. tumefaciens* strains EHA105, LBA4404, and GV3101 (Koncz and Schell, 1986), although EHA105 yielded higher frequencies of transient GUS expression than the other two. Six days cocultivation on filter paper overlaid medium yielded the highest level of transient GUS expression and did not lead to necrosis of the leaf explants. Transient GUS expression was also improved by using acetosyringone (100 μ M) and suitable medium. The blue staining cells, that were apparently susceptible to *A. tumefaciens*, were the ones active at the sites of tissue regeneration.

2.2.1.2 Cranberry

The first transgenic cranberry ‘Stevens’ was obtained using the particle bombardment method (Serres *et al.*, 1992), to which a patent (United State Patent 5240839) was issued in 1993 (<http://www.freepatentsonline.com/5240839.html>). This method was used later to produce transgenic ‘Pilgrim’ (Zeldin *et al.*, 2002). An outline of this transformation protocol is as follows. *In vitro*-derived, one-node stem sections, 5 mm, were pretreated for up to 20 days on BIM: Woody Plant Medium (Lloyd and McCown, 1980) + 0.13% D-gluconic acid + 2% sucrose + 0.3% agar + 0.1% gelrite + 10 μ M 2ip (N_6 -(2-isopentenyl)adenine) + 1 μ M TDZ (Serres *et al.*, 1992). One milligram gold particles were coated by 0.5 μ g plasmid DNA; 75 μ g DNA/bombardment was used. Stage I (2 days after bombardment): on BIM + 300 mg l^{-1} kanamycin (Km) (added before autoclaving); Stage II (3 weeks after bombardment): 5 ml overlay of 300 mg l^{-1} Km of sterile water on previous medium; Stage III (11 weeks after bombardment): on CMM + 300 mg l^{-1} for 9 days followed by a 200 mg l^{-1} Km of sterile water;

Stage IV (22 weeks after bombardment): on Km-free CMM.

Although successful, the bombardment method yielded a low frequency of transformation (0.15%). Additional efforts are therefore required to simplify the transformation protocol and improve transformation frequency. A higher shoot regeneration system now exists for five genotypes (‘Early Black’, ‘Pilgrim’, ‘Ben Lear’, ‘Stevens’, and ‘No. 35’) with 6.5–18.2 shoots/leaf (Polashock and Vorsa, 2002). Bombarded leaf explants of these genotypes could yield an improved transformation system. Particle bombardment-mediated transient transformation studies using leaf explants of these cultivars have yielded positive results, although stable transformation has not been reported (Polashock and Vorsa, 2002).

While *Agrobacterium*-mediated transformation has not been employed on cranberry, it has potential. Preliminary studies on *A. tumefaciens*-mediated transient transformation conducted by Vorsa’s group have proved that cranberry leaf explants are susceptible to *A. tumefaciens* strain EHA105 (Polashock and Vorsa, 2002). Also, leaf explants of cranberry are amenable to regeneration. Additional efforts should focus on optimizing *A. tumefaciens* infection conditions and developing effective antibiotic- or herbicide-selection systems for selective regeneration of transformed cells.

2.2.2 Cane fruit

A number of factors have been shown to play critical roles in determining regeneration and transformation rates of cane fruits including environmental conditions (Palonen and Buszard, 1998; Meng *et al.*, 2004), leaf orientation (McNicol and Graham, 1990), type of hormone (Fiola *et al.*, 1990; Millan-Mendoza and Graham, 1999), and most importantly genotype (Reed, 1990; Owens *et al.*, 1992; Graham *et al.*, 1997a). Both blackberries and raspberries have been regenerated from leaves, stem segments, and cotyledons (Hall *et al.*, 1986). Regenerate shoots of blackberry most readily form at the leaf–petiole junction from phloem parenchyma cells or cells surrounding the vascular bundles (Ke *et al.*, 1988). Protoplasts have also been isolated from various *Rubus* species, but no regenerates have been produced beyond callus

(Mezzetti *et al.*, 1999; Dunland *et al.*, 2000; Nita-Lazar *et al.*, 2000).

MS medium that is enriched with cytokinin and auxin is usually utilized for organogenesis (Swartz and Stover, 1996; Norton and Skirvin, 1997). Indole-3-butyric acid (IBA), NAA, or 2,4-dichloro-phenoxyacetic acid have been used successfully as auxins, and TDZ is the most effective cytokinin (Fiola *et al.*, 1990; McNicol and Graham, 1990). Explants are most commonly cultured in the dark for varying periods from 1 day to several weeks before being transferred into the light (Fiola *et al.*, 1990; McNicol and Graham, 1990; Meng *et al.*, 2004), and regeneration has been found to occur more readily at 20 °C than 25 °C (Turk *et al.*, 1993).

2.2.3 Strawberry

Strawberries were one of the first crops to be routinely proliferated through micropropagation (Zimmerman, 1991), and regeneration systems for *F. × ananassa* have been developed with disarmed strains of *A. tumefaciens* using anthers, callus, flower buds, leaf discs, protoplasts, petioles, stems, stipules, roots, and runners (Hokanson and Maas, 2001; Passey *et al.*, 2003). Callus, petiole sections, and leaf discs have also been used in combination with *A. tumefaciens* to regenerate *F. vesca* (Haymes and Davis, 1998; Alsheikh *et al.*, 2002). Genotypes vary widely in the success of the various techniques, and some are quite recalcitrant to all techniques. A genetic line of *F. × ananassa*, LF9, has been developed that produces transformed shoots in as few as 15 days (Figure 3; Folta *et al.*, 2006).

Most of the transgenic strawberries to date have been generated using *Agrobacterium*-mediated transformation systems. *Agrobacterium* strains LBA4404 and EHA105 have been most commonly employed, with pBIN19 derivatives as the binary vector (Graham, 2005). In most cases, leaf- or stem-based systems have been utilized in MS medium. The hormones have been BA plus 2,4-D or IAA. Regenerates have generally been selected using 25 mg l⁻¹ kanamycin, and contamination after inoculation has been limited by using cefotaxime, carbenicillin, and ticarcillin.

Biolistics have been employed in three instances with strawberry. De Mesa *et al.* (2000)

Figure 3 The progression of shoot regeneration in LF9 petiole cultured on medium supplemented with 0.05 μM 2,4-D in combination with 0.10–0.50 μM BA and 4.54 μM TDZ. (a) 0 days; (b) after 5 days; (c) after approximately 40 days; (d) a comparable explant grown in complete darkness with occasional inspection under light [Reproduced from Folta *et al.*, 2006. © Springer]

bombarded leaf discs with *Agrobacterium*-coated gold microprojectiles as a means to enhance stable transformation of GUS. Wang *et al.* (2004) bombarded strawberry calli with tungsten particles coated with the pBY520 plasmid using PDS-1000/He. Agius *et al.* (2005) used particle bombardment to effect transient transformation of strawberry fruit.

An effective marker-free transformation process has recently been successfully tested in strawberry (Schaart *et al.*, 2004). In it, a vector was constructed in which site-specific recombination left only the 35S promoter of cauliflower mosaic virus and a GUS encoding sequence. The system incorporated an inducible site-specific recombinase to eliminate the selectable marker. Fully marker-free transgenic “Calypso” plants were obtained through this procedure.

2.3 Testing

There have not been many reports on field trials of transgenic plants of *Vaccinium* species. Polashock and Vorsa (2002) mentioned in their review that field tests were conducted to evaluate transgenic “Stevens” and “Pilgrim” cranberries, both with *Bacillus thuringiensis* (*Bt*). Four transclones showed a significant increase in blackheaded fireworm (BHFw, *Rhopobota naevana*) mortality rate, although none of the 64 *Bt*-expressing transclones yielded significant BHFw larval mortality in *in vitro* feeding assays. Herbicide-resistant cranberry with *bar* was also evaluated under greenhouse and coldframe conditions; one transclone with *bar* showed moderate tolerance, 500 mg l⁻¹ glufosinate ammonium, to glufosinate-herbicide Liberty (Zeldin *et al.*, 2002). Similarly, *bar*-expressing blueberry “Legacy” showed high herbicide resistance under controlled conditions (Song *et al.*, 2007). Most recently, field trials are being conducted in Michigan to evaluate the *bar*-expressing “Legacy”; several transgenics were identified with strong herbicide resistance (Song *et al.*, 2007).

In an effort to engineer resistance to RBDV, Martin *et al.* (2004) produced 197 transgenic lines of “Meeker” red raspberry with either the coat protein gene, mutated forms of the movement protein gene, or nontranslatable RNA of RBDV. These lines were planted in a field with extreme disease pressure, and after 4 years, five lines were found to be resistant. Fruits from these lines had a similar ACY profile to those of wild type fruit.

To develop strawberry cultivars resistant to glyphosate, the *CP4.EPSP* synthase gene was introduced into “Camarosa” through *Agrobacterium*-mediated transformation. When 73 independent transformants were sprayed with

Roundup Ultra, they showed a wide range in symptoms, but 30 of them were highly tolerant. Southern analysis of the most tolerant lines showed that all but two of them had only a single copy of the *CP4.EPSP* synthase gene. The transformed, glyphosate-sprayed lines produced typical, good quality fruit.

Graham *et al.* (2002) trialed transgenic strawberries constitutively expressing the cowpea trypsin inhibitor (*CpTi*) to determine if they offered protection against feeding of the vine weevil (*Otiorhynchus sulcatus*). Over 3 years, two transgenic “Melody” and three transgenic “Symphony” lines showed significantly improved plant growth in comparison to controls and had a significant reduction in the number of pupae feeding on their roots. Yield was not assessed due to severe fruit rot, but no effects on the numbers of Carabid and other nontarget arthropods were noted.

Mezzetti *et al.* (2004) field trialed transgenic strawberries and raspberries carrying the *defH9-iaaM* auxin-synthesizing gene. The transgenic plants showed significant increases in fruit number, size, and yield. The increase in fruit yield was about 180% in cultivated strawberry, 140% in wild strawberry, and 100% in raspberry.

2.4 Specific Regulatory Measures Adapted

To date, no requests have been made for the unrestricted release of transgenic small fruit crops, and only a very limited number of field trials have been conducted. These have been conducted under the auspices of local Laboratory Biosafety Committees, the Animal and Plant Health Inspection Service (APHIS) of USDA, Food and Drug Administration (FDA), Environmental Protection Agency (EPA), State regulation, and International agreements.

3. FUTURE ROAD MAP

3.1 Expected Products

Weed infestation in fields is one of the major problems in all small fruit crops, particularly strawberry. To control weeds in many crops, nonselective and broad-spectrum herbicides, such

as glyphosate and phosphinothricin, are usually used although they can only be applied as a directed spray under the bushes and avoiding any contact with the green tissues. Herbicide-resistant plants can be expected to broaden the application of nonselective herbicides and to provide a simple, inexpensive, potent, and environmentally friendly management for weed control. Currently, two transgenic herbicide-resistant cropping systems are common for soybean, maize, rapeseed, and cotton: RoundupReady (active agent: glyphosate) and Liberty Link (active agent: glufosinate).

With the impending ban on the use of MB fumigation in strawberry production, growers have lost their most effective means to control weeds and soil pathogens. Yields in most of the cultivars now grown are reduced by 50% in nonfumigated soil, and only limited genetic variability for resistance has been found to the broad range of pathogens controlled by MB fumigation (Larson and Shaw, 1995a, b; Particka and Hancock, 2005). Herbicide-resistant strawberries with the *CP4-EPSP* synthase gene or *PAT* would allow for the effective control of weeds, and a transgene like *pcht28* that provided resistance to a broad range of fungal pathogens could restore considerable yield potential. Engineered resistance to *Phytophthora fragariae* root rot would also be extremely valuable in raspberry, as it is a major objective of all breeding programs. To minimize marketers concerns about the acceptance of transgenic fruit, targeted expression of these genes to just vegetative tissue would likely be required. The use of marker-free selection systems might also prove beneficial.

The incorporation of transgenes for fruit rot resistance and increased firmness in strawberries and raspberries, such as the antisense of genes for pectate lyase and polygalacturonase-inhibiting protein, would be highly beneficial if the public is prepared to accept them. Strawberries and brambles are a highly perishable fruit and even with controlled atmosphere storage and refrigeration, a high proportion of the harvested fruit are lost due to softening and fungal disease. In particular, *Botrytis* and *Phytophthora* infections are common sources of substantial crop losses in all of the small fruit crops.

Transgenic breeding could also provide small fruit crops with resistance to major virus diseases.

Of particular importance are raspberry bushy dwarf, blueberry stunt, blueberry shoestring, and strawberry crinkle and others in the yellows complex. In addition to expression of coat protein for protection against these diseases, application of RNAi technology could be exploited to obtain virus-resistant plants (Tenllado *et al.*, 2004; Hoffman *et al.*, 2006). Resistance to RBDV has already been engineered in raspberry through transgenic approaches, but the resistant lines have not gone through the regulatory system.

The distribution of small fruit cultivation is often restricted by low temperature stress. Frost tolerance at bloom is particularly important in all the small fruits and winter cold hardiness is often an issue, particularly in raspberries. While some genetic variability exists for these characteristics, very little improvement has been made by plant breeders. The incorporation of genes such as *CBF1* could provide the necessary genetic variability to improve this trait, if their phenotypic effects could be limited by targeting their expression to floral tissues or periods of cold (Kasuga *et al.*, 2004).

Cool temperatures during flowering also commonly limit small fruit yields. When temperatures are low during bloom, pollinator activity is greatly reduced leading to poor seed set, reduced fruit size, irregularly shaped fruits, and low yield. The incorporation of a gene that induces parthenocarpic fruiting like the *defH9-iaaM* auxin-synthesizing gene would be very beneficial in areas where cool conditions prevail during pollination.

Transgenic approaches might also be employed to modify the secondary metabolism of the small fruit crops to improve their nutritional quality and flavor (Scalzo *et al.*, 2005). Successful modification of the nutritional value of tomatoes through metabolic engineering and transformation has provided a novel example of the use of organ-specific gene silencing to enhance the nutritional value of fruits (Davuluri *et al.*, 2005). Biochemical pathways might be altered through transgenic approaches to enhance ACY production and strengthen aroma. Numerous genes have been identified in strawberries that are associated with aroma (Aharoni *et al.*, 2000, 2004) and flavonoid metabolism (Wilkinson *et al.*, 1995; Manning, 1998).

3.2 Addressing Risks and Concerns

Several obstacles are working against the acceptance of transgenic blueberries, cane fruit, cranberries, and strawberries. The economic value of these fruit crops is limited compared to many of the agronomic crops and as a result there is only modest private stimulus to develop new biotechnological products. A second issue is that they are all outcrossed crops with widespread, native relatives in close proximity to cultivated fields. Most transgenic crop releases to date have been with species that do not have nearby congeners, eliminating the risk of the movement of the transgene into wild species populations. The release of transgenic small fruit crops will require more scrutiny and in-depth ecological studies than has been necessary with those trans crops previously released (Hancock, 2003). The third issue associated with the commercial release of transgenic blueberries, cane berries, cranberries, and strawberries is reluctance by the fruit industry to introduce transgenic products, for fear that there will be a negative backlash from people leery of consuming genetically modified (GM) crops.

A strong influx of federal and state funds is needed to stimulate strawberry biotechnology research, along with a careful analysis of what people's real perceptions are about transgenic fruit. Until this happens, transgenic small fruit crops will remain an important research tool, but not a commercial entity. Utilizing marker-free transformation systems and targeted expression of transgenes will help minimize public concern, but the fear of the technology in general must be reduced before transgenic small fruit products will find their way into homes.

1. INTRODUCTION

1.1 History, Origin, and Distribution

Central Asia is the likely origin of the earliest diploid *Prunus* species (Watkins, 1976). Species in the section *Cerasus*, which includes sweet (*P. avium* L.), sour (*P. cerasus* L.), and ground (*P. fruticosa* Pallas) cherry, are thought to be derived from this ancestral *Prunus*. The *Cerasus* cherries developed to the west of the central Asian subgenus *Cerasus*' center of origin, while most other *Prunus* species evolved in the east.

Hedrick (1915) described the geographic range of wild sweet cherry as all of mainland Europe well into the southern part of erstwhile USSR and as far east as northern India, with the greatest prevalence between the Caspian Sea and the Black Sea. In contrast, the ground cherry's center of origin is western and central Asia (Watkins, 1976).

It is reported that sweet cherries were brought by the Roman General Lucullus from Cerasunt on the Black Sea to Rome in 74 BC, and they spread from there to Germany and Britain. Sweet cherries (mazzard) have been grown from southern Russia, north of the Caucasian mountains, to the north of France for centuries. The ground cherry has a wider area of distribution, which overlaps with the center of wild sweet cherry, thus giving rise to hybrids as sour cherries. The sour cherry is a native of the Carpathian Basin. Domestication

and cultivation have resulted in some ecotypes of sweet, sour, and ground cherries arising in the various areas of Europe and partly in Asia. Several sweet and sour types are adapted to harsh winter conditions (Iezzoni *et al.*, 1991; Faust and Surányi, 1997).

There is good evidence suggesting that *P. cerasus*, a tetraploid, arose from a natural cross between *P. avium* and *P. fruticosa*. The geographic ranges of the two species overlap in northern Iran and Turkmenistan, which is the center of origin of sour cherry. From there, sour cherry followed a similar course to Europe as sweet cherry, and ultimately came to North America with English settlers. It is more tolerant of the humid, rainy eastern conditions, and therefore proliferated more than sweets, where it is still cultivated today in greatest numbers. Michigan, the leading producer in North America, grows sour cherries along the eastern shore of Lake Michigan, where the moderating influence of the lake on winter and spring temperatures is beneficial to production.

Although, cultivated cherries are ubiquitous in the temperate zone, there has been little effort to take them further south into subtropical regions. Among cherry genotypes, there are cultivars that require low levels of winter chilling, although the existing high-quality cherry cultivars all have high chilling requirements. Commercial production of sweet cherries is constrained by rainfall during the ripening period, which causes cracking of

Bigarreau-type (firm-fleshed) sweet cherries as well as subsequent brown rot infection, which destroys the value of the fruit.

1.2 Botanical Features

The “true” cherries are now classified by botanists within the genus *Prunus*, subgenus *Cerasus*, family Rosaceae, rather than by the older system within the genus *Cerasus* (Webster, 1996). The subgenus *Cerasus* is divided into eight sections, and section 1, *Eucerasus*, has *P. avium*, *P. cerasus*, and *P. fruticosa*. Altogether, there are over 150 *Prunus* species.

The mature sour cherry is a medium-size tree with a rounder, more spreading habit than the erect sweet cherry. Tree height is maintained at 3 m or less in cultivation. Leaves are smaller than that of sweet cherry, elliptic with acute tips, mildly serrate margins, with long petioles. Individual flowers are the same as in sweet cherry. Sour cherry inflorescence buds usually produce 2–4 flowers, with long pedicels, as in sweet cherry. However, a higher proportion is borne laterally on 1-year wood rather than on spurs, as compared to sweets. Spurs are shorter lived on sour than sweet, gradually declining in productivity over 3–5 years. Sour cherries are the latest blooming of the stone fruits. Most sour cherries are self-fertile, and require no pollenizers. The fruit is a drupe, 20–25 mm in diameter, round or heart-shaped, glabrous, with a long pedicel attached. The pit is generally smooth, and encloses a single seed. Sour cherries generally have lower sugar and higher organic acid content than sweet cherries, giving them their distinct flavor. They are generally bright red in color, and exhibit less color variation than sweets, which are usually dark red to purple. “Montmorency” produces about two-third of its fruit laterally on longer wood, and one-third on spurs. Both sweet and sour cherries require only about 2–3 months for fruit development. No thinning is required for sour cherries, whereas sweet cherries often are pruned annually to reduce the crop load and increase fruit size.

Sour cherry is naturalized widely and its distribution area covers almost all European countries and Southwest Asia. However, it is cultivated in many additional parts of the world, mainly in North America. Both sweet and sour

cherries develop extensive root systems in deep, well-drained, gravelly to sandy-loam soils, which are optimum. Thus, aeration is more important than water-holding capacity, and flooding or heavy soils limit growth and production (Webster and Looney, 1996). Sweet cherry performance is best in cool, dry climates with limited exposure to spring frosts and diseases, and lack of rainfall during harvest. Rainfall and/or high humidity, especially at bloom or harvest, promote fungal and bacterial diseases that kill flowers and shoots or incite fruit rots. During harvest, rain causes the fruit to crack. Thus again, dry climates are preferred (Webster and Looney, 1996). These favorable environmental conditions explain why, in the United States, Washington, Oregon, and California are the leading producers. Conversely, sour cherries prefer cool, humid conditions; although they can be grown in the western US, fruit size is diminished by the arid climate. Sweet and sour cherries both require 1000–1500 h of chilling temperatures in winter; thus, they cannot be grown in warmer climates. Dormant buds are killed at about -29°C (-20°F), and the pistil is particularly sensitive to spring frosts.

The 2C value for diploid “Van” sweet cherry was reported as 0.67 pg (picogram), which is about one-half that of the tetraploid *Prunus* \times sp. “4x” of 1.36 pg, while tetraploid “Montmorency” sour cherry had a 2C of 1.42 pg (Dickson *et al.*, 1992). Twenty-six isozyme loci and one morphological trait (Tobutt and Nicoll, 1992), and 89 markers falling into 10 linkage groups (Stockinger *et al.*, 1996), have been accomplished for diploid $2n = 2x = 16$ sweet cherry. For sour cherry, $2n = 4x = 32$, restriction fragment length polymorphism maps of the cvs. Rheinische Schattenmorelle (RS) and Erdi Botermo (EB) were constructed using 86 progeny from the RS \times EB cross (Wang *et al.*, 1998). The RS map has 126 markers while EB has 95 markers in 19 and 16 linkage groups, respectively. Bridges between RS and EB were identified by 53 common markers to 13 homologous linkage groups. From a cytological perspective, sour cherry has disomic inheritance but occasional intergenomic pairing with pre- or postzygotic selection (abundant 2:1 ratios) (Beaver and Iezzoni, 1993). Mapping and expressed sequence tag (EST) data are both included in the Clemson Genome Database for Rosaceae (<http://mainlab.clemson.edu/gdr/genus/prunus/>

cherry/index.shtm). Details of genome mapping and molecular breeding have been reviewed thoroughly by Dirlewanger *et al.* (2006).

1.3 Economic Importance

Sweet cherries are grown in more than 45 countries of the world, and sour cherries in at least 35 countries (Webster and Looney, 1996). Based on the top 20 countries of production for each, world production of sweet cherries (1.86 million metric tons) is about 53% higher than that for sour cherries (1.2 million metric tons), and the worldwide sweet cherry crop value of US\$1.44 billion is about 134% higher than that for sour cherry (FAOSTAT, 2005). No single country accounts for more than 14% of world sweet cherry production (O'Rourke, 2006). The relatively short seasonality, high perishability, and delicate handling required for high-quality fresh sweet cherries likely contribute to this egalitarian worldwide production picture.

The market for fresh sweet cherries has remained very strong for more than the past decade (1995–2005), an otherwise turbulent period for most tree fruit markets (e.g., apple, peach, pear). Consequently, world harvested area of sweet cherries has been increasing dramatically, from 289 000 ha (1985) to 327 000 ha (1995) to 401 000 ha (2005), and the area actually planted to sweet cherries (but not yet bearing) is likely to be significantly higher yet (O'Rourke, 2006). The increase has been especially dramatic in North America, with a 48% increase in production area from 1995 to 2005. In terms of sweet cherry area harvested, the top countries are Spain, Germany, the United States, Italy, the Russian Federation, Turkey, and Iran. On a percentage increase basis, the most rapid increases in production area have been in the southern hemisphere regions of Chile, Argentina, Australia, New Zealand, and South Africa.

Although world production area has been increasing dramatically, actual world tonnage hit a record level (1.9 million metric tons) in 2000 but has been at a plateau between 1.8 and 1.9 million metric tons since then (O'Rourke, 2006). The top three countries of production are Turkey (260 000 t), the United States (250 000 t), and Iran (223 000 t), followed by Germany, Italy, and the

Russian Federation at about half the level of the top three. From a sweet cherry breeding point of view, this discrepancy between area planted and production suggests that significant production gains have yet to be made through improved adaptive traits associated with its many abiotic and biotic limitations.

Worldwide sour cherry production is led by the Russian Federation at a 2005 harvest of 235 000 t, followed by Ukraine (178 000 t), Turkey and Poland (about 140 000 t each), Serbia and Montenegro (116 000 t), the United States (98 000 t), and Hungary and Germany at about 81 000 t (FAOSTAT, 2005). A significant portion of the production in the Russian Federation, Ukraine, and Serbia and Montenegro is probably from “backyard” trees rather than commercially managed orchards (Webster and Looney, 1996).

The primary market value of sweet cherries is as a premium fresh product eaten out of hand, but industrial uses of processed sweet cherries are also important. The primary market value of sour cherries comes from industrial uses, though some are eaten fresh. Processed uses of sweet and sour cherries include frozen, canned, and dried forms for use in baking (e.g., pastries, pie filling, and dessert toppings); ice cream and yogurt; additives to snacks, breakfast cereals, confections, salads, etc.; juices, liqueurs, wines, and flavorings; preserves, jellies, and jams; as well as brined for maraschino cherry products.

During the past decade, both sweet and tart cherry fruits have become recognized for potential benefits to human health. Both are rich in vitamin C and potassium (Iezzoni *et al.*, 1991; Looney *et al.*, 1996) as well as multiple forms of phytochemical compounds, such as bioflavonoids and anthocyanins (Brown *et al.*, 1996). Certain forms of both of these compound groups have been shown to exhibit antioxidant and anti-inflammatory properties, including cyclooxygenase (COX-I and COX-II) inhibition comparable to over-the-counter drugs such as ibuprofen (Wang *et al.*, 1999, 2000; Seeram *et al.*, 2001; Tall *et al.*, 2004). Kang *et al.* (2003) also demonstrated inhibitory activities of tart cherry anthocyanins against colon cancer. Cherries may become a valuable nutritional supplement for human diets to help reduce the risk of, and alleviate the pain from, degenerative diseases such as arthritis (Seeram

et al., 2001). Concentrated sour cherry juice and powdered cherry extracts (in tablet form) for health consumption are additional industrial uses that are likely to increase future fruit utilization.

1.4 Traditional Cherry Breeding

The most important sweet cherry variety in North America is “Bing”, selected from a chance seedling in the late 1800s (Hedrick, 1915) for its outstanding flavor, firmness, size, and adaptation to the Pacific Northwest United States. Similarly, “Montmorency”, a seedling selected in Europe prior to the 1600s (Hedrick, 1915), has been the most important sour cherry variety in North America for more than a century, and it remains the industry standard today. Selections within commercial orchards, often by growers, of more productive “strains” of standards such as “Bing” or “Montmorency” historically have been a common tool used for genetic improvement from ancient cultures (Fogle, 1975) even to the present day. For example, in the late 1990s, commercial producers of “Lapins” sweet cherry have selected later ripening sports that subsequently have been named (“Sweet ValentineTM” and “Sweet Georgia”) and promoted commercially to extend the ripening season. The majority of the cherry rootstocks used worldwide are relatively unimproved seedlings of *P. avium*, *P. cerasus*, or *P. mahaleb*. Clearly, there is great potential for genetic improvement of sweet and sour cherries as well as rootstocks via traditional and modern breeding efforts.

1.4.1 Sweet cherry breeding objectives

Fogle (1975) noted that sweet cherries are not well adapted to many climates, therefore historical genetic improvement efforts have been localized to areas with significant production. With the rise of global trade and postharvest technologies for long-distance shipping, genetic improvement efforts in the 21st century have become, to a great extent, similar the world over. The most commonly cited sweet cherry breeding objectives are listed in Table 1 and discussed briefly below.

Self-compatible (“self-fertile”) varieties can increase orchard area productivity, since less valuable pollenizer varieties (usually about 10% of the orchard) are not needed. Similarly, variations in bloom overlap of primary and pollenizer varieties can be eliminated, thereby improving fruit set and yield consistency. Extension of the ripening season is critical for more competitive marketing, as well as for more efficient use, and better retention, of seasonal harvest labor.

Reduced susceptibility to rain-induced fruit cracking is a universal goal even in the arid regions that dominate world production, since a single rain event at the wrong time can render a high-value cherry crop unmarketable. Fruit cracking is a complex trait (which is also influenced by temperature), as genotypes can vary both in their sensitivity to rain, as well as in the developmental stage at which they are most sensitive; for example, some varieties are more susceptible to cracking early in stage III (color change from green to yellow) and others later in stage III (color change from pink to red). Consequently, this is

Table 1 Most common sweet cherry breeding objectives

Breeding objective	Breeding programs and/or reviews
Self-compatibility	Blazková, 1996; Nikolic <i>et al.</i> , 1996; Saunier, 1996; Granger, 1998; Olmstead <i>et al.</i> , 2000b; Apostol, 2005a; Kappel, 2005; Sansavini and Lugli, 2005
Extended ripening	Saunier, 1996; Olmstead <i>et al.</i> , 2000b; Apostol, 2005a; Kappel, 2005; Sansavini and Lugli, 2005
Cracking susceptibility	Blazková, 1996; Nikolic <i>et al.</i> , 1996; Saunier, 1996; Andersen, 1998; Granger, 1998; Kappel, 2005; Sansavini and Lugli, 2005
Fruit quality traits	Blazková, 1996; Saunier, 1996; Andersen, 1998; Granger, 1998; Olmstead <i>et al.</i> , 2000b; Apostol, 2005a; Kappel, 2005; Sansavini and Lugli, 2005
Yield traits	Nikolic <i>et al.</i> , 1996; Andersen, 1998; Kappel, 2005; Sansavini and Lugli, 2005

Climatic adaptations	Blazková, 1996; Brown <i>et al.</i> , 1996; Nikolic <i>et al.</i> , 1996; Andersen, 1998; Lang <i>et al.</i> , 1998
Fruit color traits	Olmstead <i>et al.</i> , 2000b; Sansavini and Lugli, 2005
Mechanical harvest	Saunier, 1996

a trait perhaps most likely to be improved where the selection pressure is greatest due to higher incidence of rain events during harvest, rather than in the more important production areas where such events are infrequent. The complexity of the trait has, thus far, made it difficult to adequately screen for in laboratory assays.

High-quality fruit is a complex of multiple traits including large size, firm flesh, intense sweet–tart flavor, and good postharvest performance. Fogle (1975) advocated a minimum average diameter of 30 mm as a strong selection criterion, since large fruits command significantly higher market prices (though not in the absence of at least threshold levels of the other traits). Firm flesh is universally desired by both shippers and consumers. The intense sweet–tart flavor of premium sweet cherries is a balance of high soluble solids, relatively high acidity, and a slight astringency; a combination of pleasing sweetness with refreshing modest tartness that results in a desire for continued consumption rather than rapid satiety. There is no standard set of measures against which quantitative data can be compared, but rather a subjective balance of sugars, acids, and subtle flavor components that must be evaluated by the breeder or a trained taste panel as a complete sensory experience in combination with flesh texture and juiciness.

Yield traits include precocity, productivity, and consistency. Precocity, or the time to first fruiting, can be altered in a number of ways—planting at higher densities (Robinson *et al.*, 2005; Seavert, 2005), use of precocity-inducing rootstocks such as Gisela 5 (Lang, 2000), use of precocity-inducing tree training or orchard management strategies (Long, 2005), use of growth regulators (Elfving *et al.*, 2003), or via genetically improved precocity of scion varieties, such as that imparted by “Van” (Fogle, 1961). The pressure for breeding programs to increase the efficiency of the breeding cycle tends to lead to selection of more precocious varieties simply to avoid the expense of maintaining seedling trees for 8–10 years to obtain initial fruiting data. Productivity is a trait best determined on a comparative basis, depending on production region. High yields tend to inversely affect fruit size; however, where yields often are limited by climatic factors (e.g., spring frosts, low winter chilling, and poor pollination conditions), genotypes with a tendency to set excessive crops

under ideal conditions may be highly desirable after all.

Resistance or high tolerance to diseases, such as brown rot (*Monilia/Monilinia* spp.), leaf spot (*Blumeriella jaapii* Rehmi), powdery mildew (*Podosphaera clandestina* (Wall.:Fr.) Lev.), *Cytospora* spp., and bacterial canker (*Pseudomonas* spp.), is increasingly a concern as synthetic pesticide use is curtailed by product availability or by the demands of the market place. While few breeders have noted insect resistance as a sweet cherry breeding objective, genetic avoidance of such pests as cherry fruit flies (*Rhagoletis* spp.), black cherry aphid (*Myzus cerasi* Fab.), and plum curculio (*Conotrachelus nenuphar* Herbst) certainly would be welcome by growers.

Traits for adaptation to specific climates vary by location, and include late bloom for frost avoidance and/or tolerance of flower buds to low spring temperatures, survival of low winter temperatures (particularly in concert with resistance to the canker-causing bacterial and fungal diseases that often interact with sublethal low temperatures to kill trees), resistance to high-temperature-induced fruit doubling in hot climates, and adaptability to climates with very little of the winter chilling temperatures required for breaking dormancy.

Although sweet cherry flesh colors range from a near lack of pigment to pure yellow to pink to bright red to dark purple, currently varieties with dark red (mahogany) flesh and skin predominate for fresh market production. However, diverse fruit color traits can expand marketing opportunities. In the past 15 years, the so-called blush-type sweet cherries—having yellow flesh and yellow skin with patches of red “blush”—have become increasingly important as a “super-premium” product that commands the highest price in many markets, thereby generating interest in this and other variations that would stand apart from standard mahogany-colored fruits.

Suitability for mechanical harvest, including uniform ripening and ease of stem detachment from the fruit, may be increasingly important as harvest labor becomes more difficult and expensive to procure. Such traits would have to be combined with other critical fruit traits like firmness, and resistance to bruising and pitting as well as perhaps with changes in tree architectural traits and improved mechanical harvest technologies.

1.4.2 Sour cherry breeding objectives

Due to their primarily industrial use, sour cherry traits such as fruit size, flavor balance, and fresh appearance are not nearly as critical as for sweet cherries (Fogle, 1975). Certainly, threshold levels of flavor components and fruit size are necessary, but high productivity and adequate fruit texture (to withstand mechanical harvest, pitting, and processing) are of greater importance. As worldwide sour cherry production and value is less than that for sweet cherries, there are fewer breeding programs actively involved in sour cherry improvement. The most commonly cited breeding objectives for sour cherry are listed in Table 2 and discussed briefly below.

Important diseases for which resistance or high tolerance would be desirable include leaf spot, *Cytospora leucostoma* (Pers.) Fr. and *Cytospora rubescens* Fr., brown rot, *Prunus* necrotic ringspot virus (PNRSV), and sour cherry yellows disease. Leaf spot is the most important disease in worldwide sour cherry production (Iezzoni *et al.*, 1991), sometimes causing complete defoliation during mid-to-late summer that can prevent normal ripening of the crop as well as predispose trees to subsequent winter injury. Extension of the ripening season facilitates more efficient utilization of harvest machinery and industrial processing capacities as well as diversifies production risks from adverse climatic events. The advantages of self-compatibility, and increased and more consistent yields, are similar to those noted above for sweet cherry.

Key traits for high-quality sour cherry fruit include having high soluble solids, dark red juice and flesh, round pits, and good flavor. Traits that confer suitability for mechanical

harvest include varieties having dwarf stature when planted on their own roots (i.e., without grafting to rootstocks), uniformity of ripening, and ease of stem detachment from the fruit. Smaller trees increase the potential options for mechanical harvest technologies as well as can lead to improved quality of mechanically harvested fruit, but they also must exhibit high productivity due to the reduction in light interception by dwarf canopies on a per area basis. Finally, desirable climatic adaptations include late bloom for frost avoidance and cold-hardiness/survival of low temperatures.

1.4.3 Cherry rootstock breeding objectives

Rootstocks are a key component of the composite plant system common to most tree fruit production, in which a fruit-bearing scion (having commercial fruit quality) is grafted onto a genetically separate rootstock having additional important traits like the ability to reduce vigor, increase productivity, or adapt to a specific soil type. Thus, the evaluative step of genetic improvement for rootstocks requires the additional step of grafting and outgrowth/fruiting of a scion, adding a minimum of several additional years to the breeding-to-release (or use as an improved parent) cycle. Programs for genetic improvement of cherry rootstocks have been relatively few, often of secondary focus, and a number of the most successful are no longer active (e.g., the Giessen program at Justus Liebig University). The most commonly cited breeding objectives for cherry rootstocks are noted in Table 3 and discussed briefly below.

The ability to confer reduced vigor to the scion variety (“dwarfing” rootstocks) is an extremely

Table 2 Most common sour cherry breeding objectives

Breeding objective	Breeding programs and/or reviews

important goal for fresh sweet cherry production. In the wild, sweet cherry is a large forest tree completely unsuitable for fruit harvest, so attaining good productivity in a small-stature tree canopy is vital for better management of leaf-to-fruit ratios, fruit quality, protection from pests, and labor efficiency (Lang, 2000). Precocity and high yields are critical for the same reasons (and including the same caveats, such as negative impact on fruit size) as noted above for these traits in scion varieties. Edaphic adaptability, such as good anchorage across soil types, tolerance of waterlogged, drought-prone, or high-pH soils, and survival (cold-hardiness) in areas with low winter temperatures are desirable rootstock traits.

Improved rootstocks should be propagated easily by cuttings (to improve the economics of producing a grafted tree), have resistance to soil-borne diseases such as *Phytophthora* and *Armillaria* root rots, and have broad graft compatibility across varieties. This latter trait, along with tolerance to pollen-borne viruses, can be problematic when hybridizations involve a broad range of *Prunus* species like *P. canescens* L., *P. maackii* Rupr., *P. fruticosa* L., *P. dawydensis* Sealy, *P. subhirtella* Miq., *P. pseudocerasus* Lindl., *P. incisa* Thunb., and *P. tomentosa* Thunb., are needed.

1.4.4 Cherry breeding tools and strategies

Standard cherry breeding techniques and strategies have changed little since being reviewed by Fogle (1975). The average breeding-to-release time for sweet cherry varieties released since 2001 (Lang, 2006b) was 20 years, with most ranging from 12 to 18 years, but some taking as long as 64 years. Pollen collection, flower emasculation, hand-pollination, protection of

hybridizations from spring frosts, etc. continue to comprise the mechanical process for manipulating genetic improvement (Brown *et al.*, 1996), but the tools available to breeders for identifying valuable parental germplasm and/or progenies have advanced since Fogle's review. Unfortunately, combining ability information on potential parents for specific cherry fruit, tree, or rootstock characters remains negligible (Brown *et al.*, 1996).

The introduction of dwarfing, precocious rootstocks has created a potential new tool for cherry breeding, making feasible the maintenance of a potted population of maternal or paternal genotypes to more easily control flowering sequences and/or to protect hand-pollinated flowers from indiscriminate insect pollinators, frosts, and diseases. Grafting or micrografting of hybrid sweet cherry seedlings onto clonal dwarfing rootstocks also can be utilized to hasten first fruit evaluation and increase breeding cycle efficiency (H. Schmidt, personal communication). Similarly, girdling of the hybrid seedling main leader during spring of the third season of growth was reported by Fogle (1975) to advance time to first fruit. Alternatively, the use of 2–3 applications of ethephon (2-chloroethylphosphonic acid) during spring to temporarily halt growth and promote first flower bud formation on own-rooted hybrid sweet cherry seedlings was used (G. Lang and D. Elfving, unpublished data) to advance the fruit evaluation cycle in the field by 1–2 years. Elite genotypes were selected 4 years after crossing, budded to precocious rootstocks, and second test fruits from multiple test sites were available for confirmation 3 years hence (i.e., 7 years after crossing), making it theoretically possible to progress from hybridization to widespread testing to commercial release in less than 10 years.

The introduction of self-compatibility has increased the potential efficiency of backcrossing

to move a desirable trait into an otherwise high-quality gene pool (Fogle, 1975), though there have yet to be any examples of this. It also must be noted that the widespread use, over the last few decades, of a single genetic source (JI 2420) for creating self-compatible sweet cherry genotypes is fraught with potential for detrimental inbreeding outcomes (Choi and Kappel, 2004).

Colchicine has been used on several occasions to double the chromosome number in sweet cherry for crossing with sour cherry (Brown *et al.*, 1996). It also has been used with *in vitro* shoot culture to create hexaploid clones of the triploid “Colt” (*P. avium* × *P. pseudocerasus* Lindl.) rootstock, for use in future breeding as well as an attempt to impart a reduction in vigor to scions (James *et al.*, 1987). The induction of mutations by irradiation has been used in both sweet and sour cherry to develop germplasm with self-compatibility (Lewis and Crowe, 1954), spur-type bearing habits, and/or compact growth habits (Fogle, 1975; Brown *et al.*, 1996).

To date, few molecular markers associated with important tree or fruit traits have been reported for marker-assisted selection in cherry scion (Iezzoni, 1996) or rootstock (Beckman and Lang, 2004) breeding efforts. Most markers developed to date have been associated with genotype identification (e.g., Clarke *et al.*, 2004). *S*-allele genotyping has made it possible to select self-compatible progeny at the seedling stage (Yamane *et al.*, 2001; Williams *et al.*, 2004), though this has not been reported to be a primary selection criterion. However, the increasingly extensive identification and molecular “fingerprinting” of many of the self-incompatibility *S*-alleles in sweet (Iezzoni *et al.*, 2005a) and to a lesser extent sour (Hauck *et al.*, 2006) cherry germplasm provide an important tool for improving breeding efficiency. Besides assuring fertility of cross-pollinations (i.e., avoiding cross-incompatibilities), this knowledge also can be used in selecting maternal and paternal parents to yield 100% progeny with self-compatibility. Should linkages ever be found between specific *S*-alleles and important traits, parental selection by *S*-allele may likewise yield efficient development of desired progeny.

Sources of disease-resistant germplasm for cherry breeding have been difficult to find. Since Fogle’s (1975) outlook on breeding for disease resistance, commercial-quality sweet and sour

varieties with partial resistance to *Monilinia* have been reported, though little resistance was found when conditions were optimized for epidemic-level colonization (Brown and Wilcox, 1989). New sour cherry varieties with improved resistance to (or tolerance of) brown rot, leaf spot, and bacterial canker have been reported recently (Schuster and Wolfram, 2004), but not yet tested in commercial settings. Several sources of resistance to foliar infection by cherry powdery mildew have been identified (Toyama *et al.*, 1993; Olmstead *et al.*, 2000a, 2001a, b). This has led to the demonstration and use of apparently durable single dominant gene resistance as a potentially useful breeding tool (Olmstead and Lang, 2002).

1.4.5 Cherry breeding achievements

In 1975, Fogle stated that breeding of cherries was at a comparatively early stage. Thirty years later, which is only 1–3 generations of perennial tree breeding cycles, there have been some important achievements, especially with regard to sweet cherry varieties having large fruit size and/or self-compatibility.

Significant advances in average sweet cherry fruit size have been made by imposing severe selection pressure, such as using a minimum average fruit weight of 10 g for retention of progeny. Consequently, a number of varieties from the Summerland (British Columbia) and Washington State University breeding programs consistently yield fruits with average weights of 11–13 g (and some individuals 18 g and larger), including “Summit”, “Glacier”, “Tieton”, “Selah”, “Sonata”, “PC 8011-3”, and “PC 7903-2” (Whiting, 2006). Recently, Olmstead (2006) has shown that fruit cell number is controlled very strongly by genetics rather than environment, suggesting that use of genotypes with high cell numbers (e.g., “Selah”) as parents may further improve sweet cherry fruit size.

The introduction of commercially important self-compatible sweet cherry cultivars began with the release of “Stella” in 1968 (Lapins, 1970), followed in 1984 by “Lapins” (Lane and Schmid, 1984), and “Sweetheart” in 1994 (Lang, 1999), all from the Summerland breeding program. Summerland has released more than a dozen self-compatible varieties thus far (Lang, 1999, 2006b),

including “Santina”, “Sandra Rose”, “Staccato” (the latest ripening self-compatible variety), “Sonata”, “Skeena”, “Symphony”, “Stardust” (a blush type), “Sunburst”, “Newstar”, “Celeste”, and “Samba”. Washington State University has released half a dozen self-compatible varieties, including “Benton” and “Selah” (designated as “Columbia” and “Liberty Bell” in Lang, 2002a), “Cashmere”, “Glacier”, “Index” (Andersen, 1997), and “PC 7147-9” (Whiting, 2006). Other self-compatible varieties that have been released in recent years include “WhiteGold” (a blush processing cherry) and “BlackGold” from Cornell University (Lang, 2002a); “Alex”, “Sándor”, “Pál”, and “Péter” from Hungary (Apostol, 2005a); “Tehranivee” and “Vandalay” from Vineland, Ontario (Lang, 1999); “Dame Nancy” (a blush type), “Dame Roma”, “Sir Don”, “Sir Douglas”, “Sir Hans”, and “Sir Tom” from South Australia (Lang, 2006b); and “Sweet Early” (the earliest ripening self-compatible variety, maturing before “Burlat”), “BlazeStar”, “EarlyStar”, “GraceStar”, “LalaStar”, and “BlackStar” from University of Bologna, Italy (Sansavini and Lugli, 2005).

The ripening season for high-quality sweet cherries has been expanded significantly during the past two decades. Dark-red mahogany cherry varieties of proven commercial export quality now encompass at least 5 weeks of ripening windows (from “Chelan” and “Tulare” to “Sweetheart” and “Staccato”), and up to 8 weeks with newly released varieties that have yet to be tested in the commercial export market chain. The potential ripening window for high-quality blushed yellow cherries also has expanded from the single mid-season variety “Rainier” to the recently released “Early Robin”, “PC 8011-3”, “Royal Rainier”, “Dame Nancy”, and late-ripening “Stardust”. These advances have strengthened international sweet cherry supply and demand due to improved competition for retail shelf space, a more orderly supply for marketing, and a risk-diversified product portfolio for growers. In other words, the success of new sweet cherry cultivars that are large, often self-fertile, and spread economic risks have most certainly helped to drive the strong international growth in sweet cherry planting noted above in Section 1.3.

Advances in resistance to rain-induced fruit cracking of sweet cherries have been only

slight, with Andersen (1998) noting “Adriana”, “Regina”, and “Sam” as significant. Likewise, only a few new sweet cherry varieties have been developed thus far with fruit that form abscission zones for easy detachment at the pedicel–spur junction (“Andersen”) or at the fruit–pedicel junction (“WhiteGold”), which are critical for improving mechanical harvest efficiency and postharvest quality.

Advances in cherry disease resistance also have been incremental at best. Monogenic resistance to cherry leaf spot has been introgressed from *P. maackii* into a selection known as “Atlant” that has good fruit size and can be hybridized with either sweet or sour cherry (Brown *et al.*, 1996). The same authors also reviewed the reported progress in developing varieties with bacterial canker resistance to at least some pathovars of *Pseudomonas morsprunorum*. However, the causal agent of bacterial canker in North America is *P. syringae*, and no broad source of resistance to multiple *Pseudomonas* species and pathovars has yet been identified. Recently, Olmstead and Lang (2002) identified a sweet cherry source of dominant monogenic immunity to foliar infection by powdery mildew, which they have used to create elite breeding selections with resistance and commercial-level fruit quality that are now in advanced stages of evaluation for commercial industry release (M. Whiting, personal communication).

Brown *et al.* (1996) noted that “the impact of sour cherry improvement in Europe and Russia has been dramatic. . . (yet) sour cherry breeding in the United States has not yet impacted the industry, which is still heavily reliant upon “Montmorency”. This remains the case in 2006. Of particular impact in Europe has been the expansion of the ripening period to 40 days (Iezzoni *et al.*, 1991) and the adoption of varieties that are suitable for both processed products and fresh markets.

1.5 Limitations of Conventional Breeding and Rationale for Transgenic Breeding

The periodic Brooks and Olmo Registers of newly released fruit and nut varieties (largely in North America) indicate that commercial cherry variety releases during the past 15 years include only five new varieties of sour cherry (Andersen, 1994, 1997;

Iezzoni, 2002; Bors, 2005) while there have been 63 new sweet cherries (Andersen, 1994, 1997; Lang, 1999, 2002a, 2006b) and 21 new cherry rootstocks, most of which originated in European rootstock breeding programs (Andersen, 1997; Lang, 2002b, 2006a). Improved sweet and sour cherry genetic output is similar in Europe (Apostol, 2005a, b). This is a reflection of both the greater number of sweet cherry breeding programs, and the more extensive and valuable sweet cherry industries worldwide, relative to that for sour cherries. However, to some extent, it may also reflect greater genetic challenges for improvement of the tetraploid sour cherry (A. Iezzoni, personal communication) compared to the diploid sweet cherry. The number of active cherry breeding programs has declined worldwide during the past half-century, ostensibly a result of declining public funding and institutional support for long-term genetic improvement of what is a relatively minor fruit crop on an international level (O'Rourke, 2006). At present, the only active public breeding programs remaining in North America for sweet cherries are in Washington and British Columbia, with two active private programs of significance (both in California), and the only active public programs for sour cherries are in Michigan and Saskatchewan.

Even though the development of improved sweet cherries has been relatively prolific, the genetic diversity of these new varieties is fairly narrow. In North America, coefficients of co-ancestry are more than twice as high for self-compatible varieties as for those that are self-incompatible (Choi and Kappel, 2004), since all self-compatible varieties have been derived from a single progenitor source of self-compatibility ("JI 2420"). Yet, nearly one in five self-incompatible varieties also have a greater than half-sibling (0.125) relationship to self-compatible varieties. Continued use of such parents will increase the potential for inbreeding depression and limit long-term genetic improvement (Andersen, 1998) unless greater genetic diversity cannot only be accessed, but utilized efficiently. This can be a major challenge due to the inefficiencies of traditional breeding technologies for long-lived perennials such as cherry trees, the continuing decrease in government support for long-term public breeding programs, and the prohibitive costs for (and economic pressures on) private

breeders to undertake extensive introgression of new genetic diversity from germplasm having potential negative traits along with valuable genetic potential.

In 1998, Andersen stated, "Cherry breeders have failed miserably in improving some critically important traits. Why? ... they have not culled rigorously enough in large enough populations, ... have not used diverse enough base populations, ... have lacked sufficient knowledge of the physiology and genetics of some primary traits." To date, precise knowledge of the heritability of many key cherry traits remains incomplete—for example, winter hardiness, fruit shape, most disease susceptibilities, precocity, graft compatibility, and rain-induced fruit cracking, to name but a few. Improvement in many of these quantitatively inherited traits is confounded by the continuing lack of physiological knowledge underlying each phenomenon, such as the case for fruit cracking or adaptation to localized climatic limitations like low winter chilling or heat-induced fruit doubling. Breeding programs that have been most successful—for example, Summerland, Washington State University, and Cornell University—have benefited from close interactions between breeders, physiologists, pathologists, and horticulturists.

Fogle (1975) suggested that most advances in disease resistance would likely have to come from species other than sweet or sour cherry. Twenty years later, Brown *et al.* (1996) reported few advances in either disease or insect resistance. As noted above, other than for powdery mildew, advances in disease resistance remain slight, and no genetic resistance to insects has yet been reported. In sweet cherry, sources of durable resistance have yet to be identified for brown rot, bacterial canker, *Verticillium* wilt, cherry fruit fly, or plum curculio as well as viruses (such as little cherry or rugose mosaic) or viruslike diseases (such as X-disease). Some interspecific rootstock genotypes are lethally sensitive or hypersensitive to Prune dwarf virus (PDV) and/or PNRSV (Lang and Howell, 2001), but these diseases can cause subtle changes in tree productivity even when the genotype is tolerant. In sour cherry, resistance to leaf spot has yet to be transferred to commercially viable genotypes.

Adaptability of cherry rootstocks to a broader range of soil types, moisture profiles, and fertility

levels has yet to be addressed significantly. Broadening climatic adaptations of scion varieties or rootstocks is likely to be a breeding efficiency challenge, requiring many breeding cycles before significant advances can be made in concert with commercially viable fruit qualities or desirable rootstock traits. In the case of interspecific hybrid cherry rootstocks as well as attempts to introgress traits such as certain disease resistances or climatic tolerances from other *Prunus* species into sour or sweet cherry varieties (e.g., Downey, 1999), fertility and fruit set can be a major impediment to traditional breeding strategies. Beckman and Lang (2004) have noted “many rootstock programs release materials that are functionally genetic dead-ends.”

The potential for modifying currently important and distinctive commercial varieties, such as “Bing” or “Rainier” sweet cherry or “Montmorency” sour cherry, with secondary traits important for future production strategies, such as mechanical harvest, or the need for resistances against difficult-to-control insects and diseases to better facilitate reduced pesticide or organic production systems, remains distant. Many of these potential improvements may well be dependent on biotechnological approaches to overcome genetic and/or breeding efficiency barriers.

2. CHERRY IMPROVEMENT THROUGH GENETIC TRANSFORMATION

Of more than 30 cherry species, genetic transformation has been reported only for several commercially important genotypes, including sour cherry, chokecherry (*P. virginiana* L.), and the cherry rootstocks “Rosa” (*P. subhirtella autumnno*), “Gisela 6” (*P. cerasus* × *P. canescens*), “Colt” (*P. avium* × *P. pseudocerasus* Lindl.), “Inmil” (*P. incisa* Thunb. × *P. serrula* Franch.), and “Damil” (*P. dawcyckensis* Sealy) (da Cãmara Machado *et al.*, 1995; Druart *et al.*, 1998; Gutiérrez-Pesce *et al.*, 1998; Dolgov and Firsov, 1999; Song and Sink, 2005, 2006a, b). The majority of cherry species, including sweet cherry, are still considered recalcitrant to transformation due principally to their recalcitrance to *in vitro* regeneration. Reliable transformation methodologies require efficient gene delivery, effective selection, and efficient plant

regeneration systems, and generally need to be optimized for individual genotypes.

2.1 Cherry Plant Regeneration

Although the floral dip method allows the production of transgenic *Arabidopsis* without plant tissue culture or regeneration (Clough and Bent, 1998), *in vitro* tissue culture and plant regeneration are requisite steps in methodologies for stable transformation of other plant species, including cherry. There have been several early reports on plant regeneration from callus suspensions and/or protoplasts of sour cherry (Durzan, 1985; Ochatt and Power, 1988; Ochatt, 1990), wild sweet cherry (Ochatt, 1991), and “Colt” rootstock (Ochatt *et al.*, 1987). However, these suspension cell- and protoplast-based regeneration systems have not led to eventual successful transformations. With the development of gene delivery technology, *Agrobacterium*- and biolistic-mediated approaches, the application of the protoplast-based method has diminished (Ochatt and Patat, 1995; Davey *et al.*, 2005). Thus, cherry regeneration systems independent of protoplasts set the basis for further studies on *Agrobacterium*- and biolistic-mediated transformation.

Cherry regeneration is determined by factors that are both biotic factors, including genotype and explant type, and abiotic, such as culture media and environmental conditions. Although plant cell totipotency theoretically enables any of the cells to retain the ability to regenerate whole new plant through organogenesis and/or somatic embryogenesis after induction by a complex number of stimuli, regeneration capacity of plant cells usually varies between species, cultivars, and explant types due to the fact that such cells might not be competent to express totipotency under a particular set of experimental inductive conditions (Ganeshan *et al.*, 2002; Su, 2002). As summarized in Table 4, 48 genotypes from 6 cherry species regenerated plants from cotyledons (4), leaf explants (45), and internode sections (5). Only 8 of the 48 genotypes had over 50% regeneration frequencies and the mean number of shoots per explant varied between 0.6 and 4.7, thereby indicating that cherry plant regeneration varied among genotypes and most might not be amenable for *in vitro* plant regeneration. Accordingly, further

Table 4 Cherry regeneration systems

Common name	Species	Genotype ^(a)	Explant	Orientation	Regeneration		Medium	Reference

optimization of regeneration protocols is still required for most cherry genotypes.

2.1.1 Genotype and explants

As reviewed by Ganeshan *et al.* (2002) and Su (2002), both genotype and explant type are very important factors and should be considered prior to plant regeneration studies. The choice of genotype is not usually as flexible as that of explant type due to the consideration of improving cultivars already in production. Cotyledons and hypocotyls are usually regenerative, readily available, and thus widely used to regenerate herbaceous plants. There have been two reports on cherry plant regeneration using cotyledons as explants (Mante *et al.*, 1989; Tang *et al.*, 2000). For seedling-propagated genotypes, cotyledon and hypocotyls are excellent for regeneration as well as for later transformation. However, most commercial genotypes of cherry are propagated vegetatively.

Therefore, leaves have been the major explant for cherry regeneration (Table 4). In the only regeneration attempt using internode sections, Matt and Jehle (2005) recently reported that the regeneration efficiency was 2x (“Regina”) and 5x (“Schneiders”) higher when using internode sections instead of leaf explants. In terms of regeneration ability, there is no question that tender internode sections are a potential explant for efficient regeneration due to the active dividing cells in its vascular tissue. Internode sections have been found to be preferable to leaf explants for regeneration, as well as for transformation, in sweet potato (Song *et al.*, 2004). Although internode sections of cherry, 2.0–3.0 mm in length \times 1.0–2.0 mm in diameter as used by Matt and Jehle (2005), are not easily available from *in vitro* plants or shoots, their high regeneration potential makes them more attractive for future attempts on regeneration and transformation.

In vitro cultures of cherry were the only source of leaf explants in previous reports and will continue to be an excellent source in the future (Table 4). Leaf explants from actively proliferating shoots showed high regeneration potential. Several reports have addressed the importance of leaf size, orientation, and wounding for adventitious shoot regeneration (Yang and Schmidt, 1992; Grant

and Hammatt, 2000; Bhagwat and Lane, 2004; Song and Sink, 2005). Whole-leaf explants with wounded midribs were used in 7 of 12 reports and showed higher regeneration efficacy than leaf sections (Bhagwat and Lane, 2004; Song and Sink, 2005). Incubation of whole-leaf explants with the abaxial surface down enabled the midribs to contact the medium and thus was used in most of the reports. In addition, early studies have shown that wounding of the midrib of leaf explants tends to promote adventitious shoot production. Shoot regeneration from wounded margins of leaf sections from “Montmorency” sour cherry was not successful (Song and Sink, 2005), whereas Espinosa *et al.* (2006) reported that adventitious shoot regeneration occurred at wounded margins as well as at the leaf midrib of black cherry.

Based on these previous reports (Table 4), the characteristics of leaf explants that are amenable for cherry regeneration can be described: (1) whole-leaf explants, 0.5–2.0 cm in length, are excised from *in vitro*, actively proliferating shoots; (2) 3–5 slices on leaf explants are made partially transverse and equidistant through the midrib; (3) leaf explants are placed with abaxial surface in contact with the medium.

2.1.2 Culture medium

The composition of the basal media plays a major role in both successful *in vitro* shoot cultures and plant regeneration. For shoot proliferation, two major basal media, Murashige and Skoog (1962) (MS) and Quoirin and Lepoivre (1977) (QL), usually are used. MS was used in 7 of 10 reports (Hammatt and Grant, 1998; Grant and Hammatt, 2000; Tang *et al.*, 2002; Bhagwat and Lane, 2004; Matt and Jehle, 2005; Espinosa *et al.*, 2006; Song and Sink, 2006a), and QL was used in the others (Yang and Schmidt, 1992; Dolgov, 1999; Song and Sink, 2005). QL works well for efficient proliferation of “Montmorency” sour cherry, and both QL and MS work for “Gisela 6” rootstock. MS was used to maintain 11 sweet cherry and 6 rootstock genotypes, although it did not lead to efficient shoot proliferation for each genotype (G. Song and K. Sink, unpublished data). In addition, woody plant medium (WPM) (Lloyd and McCown, 1980) may have potential for further improvement of shoot proliferation. For

shoot regeneration from leaf explants, WPM was the major basal medium used in 7 of 10 reports (Table 4).

Plant growth regulators (PGRs) are important stimuli for both shoot proliferation and regeneration. For shoot proliferation, 6-benzylaminopurine (BAP) has been used either alone or supplemented with additional auxins, such as indole-3-butyric acid (IBA) or 1-naphthaleneacetic acid (NAA) and gibberellic acid (GA₃), for most cherry genotypes tested. The working concentrations of these PGRs are usually 4.4 μM for BAP, 0.49 μM for IBA, 0.54 μM for NAA, and 1.45 μM for GA₃. For shoot regeneration, either thidiazuron (TDZ) or BAP, each combined with NAA or IBA, is used in most regeneration media (Table 4). Most of the previous studies have shown that TDZ was more effective for shoot regeneration than BAP (Hammatt and Grant, 1998; Bhagwat and Lane, 2004; Matt and Jehle, 2005; Espinosa *et al.*, 2006), whereas two other reports indicated BAP was more effective than TDZ in promoting shoot regeneration in some genotypes (Figure 1a) (Tang *et al.*, 2002; Song and Sink, 2006a). A low level (0.45 μM) of TDZ-pretreatment of leaf explants stimulated adventitious shoot regeneration of “Montmorency” sour cherry (Figure 1b) (Song and Sink, 2005). Variations in culture responses of leaf explants to TDZ or BAP might be related to genotype.

Carbohydrate, agar, and pH also are important factors for *in vitro* culture. To date, sucrose

(58.4–116.8 μM) has been the major carbon source used for cherry proliferation and regeneration, although sorbitol was found to be more effective than sucrose in promoting shoot regeneration from internode sections instead of leaf explants of “Sweetheart” sweet cherry (Matt and Jehle, 2005). Different types of agar affected shoot proliferation (G. Song and K. Sink, unpublished data); thus, attempts on different agar types might be an option to optimize shoot regeneration. According to previous reports, the suitable pH for cherry cultures generally ranges from 4.8 to 5.8.

Addition of timentin, cefotaxime, or carbenicillin in regeneration medium is usually required for *Agrobacterium*-mediated transformation. However, little attention has been given to the effect of these antibiotics on cherry shoot regeneration. Further studies are still required to determine suitable antibiotics that result in no or minimal inhibition of shoot regeneration at its working concentration.

2.1.3 Environmental conditions

Although light and temperature are important factors in tissue culture, they have not been given much attention for cherry shoot proliferation or regeneration. Culture temperature generally was set to 25 °C in most of the previous reports. Several studies have shown that a 16/8 h light/dark photoperiod regime yielded higher regeneration frequencies than continuous darkness (Yang and

Figure 1 Optimal adventitious shoot regeneration from leaf explants of cherry rootstock “Gisela 6” (a) and sour cherry “Montmorency” (b); (a) eight-week culture on WPM + 8.9 μM BAP + 4.9 μM IBA; (b) eight-week culture on QL + 13.3 μM BAP + 2.7 μM NAA following a 24-h TDZ-pretreatment in liquid MS + 0.45 μM TDZ [Reproduced from Song and Sink (2005, 2006a)]

Schmidt, 1992; Bhagwat and Lane, 2004; Matt and Jehle, 2005). Espinosa *et al.* (2006) found that leaf explants incubated on medium in the dark for 3 weeks before transferring to a 16-h photoperiod yielded the best regeneration results for black cherry. A few reports have documented the effect of light quality on cherry regeneration. More investigation seems required to determine optimal temperature and light conditions for efficient shoot regeneration.

2.1.4 Rooting

Although rooting of adventitious shoots derived from leaf explants was achieved for several cherry genotypes, it has not been a major focus in most cherry regeneration reports (Tang *et al.*, 2002; Bhagwat and Lane, 2004; Song and Sink, 2005; Espinosa *et al.*, 2006). In general, rooting frequency is related to genotype as well as culture conditions. Rootstocks are generally amenable for rooting. Half MS, half QL, or WPM combined with IBA or NAA appears effective for rooting of most cherry genotypes.

2.2 Cherry Transformation

Similar to most woody fruit species, genetic transformation of cherry species is currently limited to only a few genotypes (reviewed by Petri and Burgos, 2005). Since the first transgenic cherry rootstock, “Rosa”, was obtained in 1995 (da Cãmara Machado *et al.*, 1995), there have been several publications on genetic transformation of cherry species (Table 5) (Druart *et al.*, 1998; Gutiérrez-Pesce *et al.*, 1998; Dolgov and Firsov, 1999; Song and Sink, 2005, 2006a, b). These studies have shown the possibility of genetic modification of cherry species through transformation and indicate that additional efforts are required to achieve successful stable transformation protocols for the wide range of cherry cultivars.

2.2.1 Gene delivery systems

Two major methodologies, *Agrobacterium*- and biolistic-mediated transformation, have been attempted to deliver foreign genes into cherry cells

(Table 5). The biolistic method, which allows efficient gene delivery to plant cells independent of plant species, is generally associated with problems such as the requirement for expensive devices and occurrence of multiple copies of transgenes in the transgenic plants. Thus, it is used mostly for transformation of species that are recalcitrant to infection by *Agrobacterium*. In the only report on biolistic-mediated transformation of three cherry genotypes, the transgenes were delivered into meristems but no stable transgenic plants were obtained (Druart *et al.*, 1998). Compared to the biolistic method, the multiple advantages of *Agrobacterium*-mediated transformation, such as low cost, ease of handling, and allowing for production of transgenic plants with single copy insertions, have made it the favored option to produce transgenic plants. Both *A. tumefaciens*- and *A. rhizogenes*-mediated transformation have yielded stable transgenic cherry plants (Table 5).

Using *A. rhizogenes*, Gutiérrez-Pesce *et al.* (1998) obtained transgenic plants of the cherry rootstock “Colt” containing the nondisarmed pRi1855 T-DNA (transfer DNA), but the possibility of chimera transformants was not excluded. In contrast, Druart *et al.* (1998) obtained only chimera regenerants from the cherry rootstocks “Damil” and “Inmil” (Druart *et al.*, 1998).

A. tumefaciens strains have yielded the most successful transformations of cherry species (Table 5). Da Cãmara Machado *et al.* (1995) obtained the first transgenic cherry rootstock, “Rosa”, using *A. tumefaciens* strain LBA4404 (Hoekema *et al.*, 1983), and stable transformation was confirmed by Northern blot analysis. Following the method described by da Cãmara Machado *et al.* (1995), transformation of “Inmil” rootstock was reported although no information is available to confirm stable transformation. Similarly, four *A. tumefaciens* strains were tested for transformation of a sour-sweet hybrid; 3 of 58 regenerants selected with 5 mg l⁻¹ hygromycin were β -glucuronidase (GUS) positive, but molecular studies of the regenerants were not reported (Dolgov and Firsov, 1999). Using transient GUS gene (*gusA*) expression studies, three different opine-type *A. tumefaciens* strains, EHA105 (Hood *et al.*, 1993), LBA4404 (Hoekema *et al.*, 1983), and GV3101 (Koncz and Schell, 1986), were evaluated for gene delivery to cherry explants

Table 5 Summary of cherry transformation systems

Transformation methodology	Genotype	<i>Agrobacterium</i> strain	Explant type	Selectable marker gene	Selection agent	Target gene or screenable marker	Transgene detection	Reference
Biolistic	Rootstock "Inmil" (<i>P. incisa</i> Thunb. × <i>P. serrula</i> Franch.) and "Damil" (<i>P. dawydensis</i> Sealy), sweet cherry (<i>P. avium</i> L.) "Summit"	—	Meristem	<i>bar</i>	None	<i>gusA</i>	No stable transformants were confirmed	Druart <i>et al.</i> , 1998
<i>A. rhizogenes</i>	Rootstock "Inmil" and "Damil", sweet cherry (<i>P. avium</i> L.) "Summit"	ATCC pRi15834	Meristem	<i>bar</i>	None	<i>gusA</i>	No stable transformants were confirmed	Druart <i>et al.</i> , 1998
<i>A. rhizogenes</i>	Rootstock (<i>P. avium</i> × <i>P. pseudocerasus</i>) "Colt"	NCPPB pRi1855	Shoot	None	None	pRi1855 T-DNA	Transformants were confirmed by Southern blot	Gutiérrez-Pesce <i>et al.</i> , 1998
<i>A. tumefaciens</i>	<i>P. subhirtella</i> Miq. "Rosa"	LBA4404	Embryogenic callus	<i>nptII</i>	75 mg l ⁻¹ Km	<i>gusA</i>	Plants from one transgenic event were confirmed by northern blot	Da Câmara Machado <i>et al.</i> , 1995
<i>A. tumefaciens</i>	Sour cherry (<i>P. cerasus</i> L.) "Montmorency"	LBA4404 GV3101 EHA105	A whole leaf with four cuts	<i>nptII</i>	None	<i>gusA</i>	Transient GUS expression	Song and Sink, 2005
<i>A. tumefaciens</i>	Sour cherry "Montmorency" and rootstock (<i>P. cerasus</i> L. × <i>P. canescens</i> L.) "Gisela 6"	EHA105	A whole leaf with four cuts	<i>nptII</i>	1) 50 mg l ⁻¹ Km or 2) Km at 25 mg l ⁻¹ followed by 50 mg l ⁻¹	<i>gusA</i>	Transgenic events were confirmed by Southern blot	Song and Sink, 2006a, b
<i>A. tumefaciens</i>	Sour-sweet cherry hybrid (<i>P. fruticosa</i> Pall. × <i>P. avium</i> L.)	GV3101	Leaf piece	<i>hpt</i>	10 mg l ⁻¹ Hyg	Antifreeze protein gene (<i>afp</i>)	<i>Hpt</i> and <i>AFP</i> were detected by PCR in one transgenic line	Dolgov, 1999; Dolgov and Firsov, 1999
<i>A. tumefaciens</i>	Sour-sweet cherry hybrid (<i>P. fruticosa</i> Pall. × <i>P. avium</i> L.)	GV3101	Leaf piece	<i>hpt</i>	None selection for 3 weeks followed by 5 mg l ⁻¹ Hyg	<i>gusA</i>	Transgenic events were PCR- and/or GUS positive	Dolgov, 1999; Dolgov and Firsov, 1999

(Song and Sink, 2005). Cherry explants were found susceptible to *A. tumefaciens* (C58C1 pGV3850) carrying the p35SGUSIntron binary vector (Pratesi *et al.*, 2004). Cherry leaf explants, including “Montmorency” sour cherry, “Gisela 6” cherry rootstock, and all five sweet cherry varieties tested, were susceptible to all strains. Similar to reports in rice (Li *et al.*, 1992), chrysanthemum (Boase *et al.*, 1998), and conifer (Humara *et al.*, 1999), the agropine-type strain EHA105 yielded larger expression areas, stronger intensity of GUS staining and more GUS foci per explant than the other two strains. Recently, stable transgenic plants of “Montmorency” and “Gisela 6” were obtained after inoculation of leaf explants with strain EHA105 (Song and Sink, 2006a).

Numerous factors influence transient *gusA* expression including *Agrobacterium* strain, plasmid type, time of inoculation and/or co-cultivation, and temperature and environmental conditions at various stages. A 2-day co-cultivation time was used for *A. rhizogenes* transformation of the cherry rootstock “Colt” by Gutiérrez-Pesce *et al.* (1998). A 3-day co-cultivation time was adopted for *A. tumefaciens* transformation of selected sour and sour-sweet hybrid cherry cultivars (Dolgov, 1999). Song and Sink (2005) used transient expression studies to determine optimal parameters for *A. tumefaciens* gene delivery systems. Using a bacterial density of 0.5 (OD₆₀₀) in the presence of 100 µM acetosyringone and a 4-day co-cultivation yielded efficient transient *gusA* expression without causing leaf explant necrosis or resulting in bacterial overgrowth in subsequent culture (Song and Sink, 2005). These results offer the following guidelines for conducting *A. tumefaciens* stable transformation of cherry genotypes: (1) explants: freshly prepared leaf explants; (2) *Agrobacterium* strain: EHA105, LBA4404, or GV3101; EHA105 is preferable; (3) bacterial suspension: bacterial pellet is suspended to OD₆₀₀ = 0.5 in liquid co-cultivation medium supplemented with 100 µM acetosyringone; (4) infection: 30 min at 28 °C; (5) co-cultivation medium: the same as the optimized regeneration medium, or a medium that can lead to active cell division; (6) co-cultivation: leaf explants are placed on filter paper overlaid on agar-solidified co-cultivation medium plus 100 µM acetosyringone for 4 days at 25 °C in the dark.

2.2.2 Tissues competent for transformation and regeneration

Competent cherry plant cells for transformation should be easy to regenerate, susceptible to *Agrobacterium*, and readily available. Three explant types, embryogenic calluses, shoot tips, and whole leaves, have been used to produce transgenic cherry plants (Table 5). Embryogenic callus is not easily available for most cherry species. Shoot tips might yield chimeral regenerants. Whole-leaf explants are the major explant type due to the fact that wounded midribs contain competent cells for transformation, and regeneration is adventitious (Song and Sink, 2005, 2006a). In addition, tender stem sections are a potential explant source of competent plant cells for both transformation and regeneration. For cherry species that are proliferated through seedlings, the cotyledon is an excellent explant.

2.2.3 Selection of transformed tissues

Recovery of transgenic plants requires an effective selection system by which the shoots are derived from a single to a few transformed cells. Regardless of the rapid development of strategies for production of marker-free transgenic plants, marker gene-assisted selection is usually required for successful transformation of most plant species. Recently, application of different selectable marker genes for plant transformation has been well documented (reviewed by Miki and McHugh, 2004). Three major selectable marker genes, including that for neomycin phosphotransferase II (*nptII*)-kanamycin (Km) resistance, the hygromycin phosphotransferase gene (*hpt*)-hygromycin (Hyg) resistance, and the bialaphos resistance gene (*bar*)-phosphinothricin, usually are used for selection. For cherry transformation, *nptII* yielded stable transgenic plants (Table 5). In the only report where *hpt* was used as a selectable marker for cherry transformation, Dolgov (1999) obtained polymerase chain reaction (PCR)-positive transformants using *hpt* instead of *nptII* under different selection regimes. However, in this case, no evidence indicated that *hpt* was preferable to *nptII*. Druart *et al.* (1998) attempted to transfer the *bar* gene into two cherry rootstock cultivars using biolistic and *A. rhizogenes* methods;

however, *bar* was not used as a selectable marker during the production of transformants since no screening agent was applied. All three major selectable marker genes, *hpt*, *nptII*, and *bar*, could be used for cherry transformation.

An effective selection system depends on not only selectable marker genes, but also suitable selection regimes. In general, selectable marker genes are under the direction of constitutive promoters. Different promoters might yield different expression levels of marker genes. In addition, expression of a marker gene is also affected by selection conditions such as culture medium, dose of a selection agent, and environmental conditions. Determination of the optimal dose of selection agent should be carried out under the optimized regeneration conditions, and antibiotic(s) used to eliminate residual *Agrobacterium* cells. Using $75 \text{ mg l}^{-1} \text{ Km} + 250 \text{ mg l}^{-1}$ carbenicillin, da Câmara Machado *et al.* (1995) obtained one transgenic event for “Rosa” rootstock. When cefotaxime at 500 mg l^{-1} was used, selection with Km at 25 mg l^{-1} followed by 50 mg l^{-1} yielded no transgenic plants, whereas selection with Hyg at either 10 mg l^{-1} or 5 mg l^{-1} resulted in the production of transgenic plants (Dolgov, 1999). Using 250 mg l^{-1} timentin, a one-step selection with 50 mg l^{-1} Km and a two-step selection using Km at 25 mg l^{-1} for 4 weeks followed by 50 mg l^{-1} both yielded stable transgenic plants from “Montmorency” sour cherry and “Gisela 6” cherry rootstock (Figure 2) (Song and Sink, 2006a, b). The two-step selection method eventually improved transformation frequencies although it was associated with an increase in the number of escapes (Song and Sink, 2006b). The following factors might have contributed to the successful selection: (1) several washes of leaf explants using 500 mg l^{-1} timentin after co-cultivation is an effective option to remove excess bacterial cells, thereby allowing a low level of timentin (250 mg l^{-1}) for effective control of bacterial overgrowth during selection; (2) the whole selection process is performed under optimal regeneration conditions; (3) a selection regime starting with a lower level of Km followed by a higher level is an option to improve transformation frequency.

There are also some screenable marker genes that can assist selection of transformed tissues without addition of selectable agents (Miki and

McHugh, 2004). For cherry transformation, transgenic plants of “Colt” rootstock were produced from the roots obtained after using *A. rhizogenes* nondisarmed pRi1855 T-DNA (Gutiérrez-Pesce *et al.*, 1998). However, this method can lead to production of chimera transformants (Druart *et al.*, 1998).

2.2.4 Regeneration of whole plants and characteristics of transgenic plants

For a regeneration system based on somatic embryogenesis, whole transgenic plantlets can be produced after inoculation, selection, and the germination of somatic embryos. Three previous reports have documented regeneration of transgenic cherry plants through somatic embryogenesis following Km selection (da Câmara Machado *et al.*, 1995; Druart *et al.*, 1998) or nonselection (Gutiérrez-Pesce *et al.*, 1998). For regeneration systems through callus-mediated production of adventitious shoots, a necessary step for obtaining transgenic plants is to root those selected shoots. These transformation systems allowed production of Km-resistant shoots after selection on regeneration medium (Song and Sink, 2006a, b). When these shoots were proliferated on stock culture medium (QLBI) + 50 mg l^{-1} Km + 250 mg l^{-1} timentin, transgenic shoots continued to grow and proliferate, whereas the escapes stopped growing. In addition, proliferated shoots could be rooted easily on WPM + $5.4 \mu\text{M}$ NAA + 50 mg l^{-1} Km (Song and Sink, 2006a, b).

Morphology of the transgenic plants is related partly to the introduced transgenes. Expression of the nondisarmed pRi1855 T-DNA in the “Colt” rootstock yielded the expected abnormal phenotypes such as enhanced rooting capacity, shortened internodes, and wrinkled leaves (Gutiérrez-Pesce *et al.*, 1998). Abnormal phenotypes associated with the expression of marker genes such as *nptII*, *hpt*, and *gusA* have not been reported in cherry plants. No studies to date have investigated the stability of transgenes in the sexual progeny of cherry plants. Using histochemical GUS assay, staining was detectable in all tissues of transgenic shoots even after five subcultures (G. Song and K. Sink, unpublished data), indicating the stable expression of *gusA* during vegetative proliferation.

Figure 2 Histochemical GUS assays in transformed plant tissues after one-step selection with 50 mg l^{-1} Km; (a) GUS expression in uninoculated (upper) and inoculated (lower) leaf explant tissues of “Montmorency” after 8-week culture on selection medium; (b) recovery of Km-resistant shoots of “Montmorency” after 12-week selection; (c) recovery of Km-resistant shoots of “Gisela 6” after 12-week selection (arrows—adventitious shoot(s)); (d) regrowth of shoots regenerated from an inoculated leaf explant of “Gisela 6” on QLB1 (QL+ $2.2 \text{ } \mu\text{M}$ BAP + $0.25 \text{ } \mu\text{M}$ IBA) containing 50 mg l^{-1} Km and 250 mg l^{-1} timentin—(1) a shoot with GUS-negative leaves and (2) a shoot with GUS-positive leaves; (e) rooted transgenic plants (1 and 2) and nontransformed plant (N) of “Montmorency” before (upper) and after (lower) GUS staining; (f) rooted transgenic plants (1, 2, and 3) and nontransformed plant (N) of “Gisela 6” before (upper) and after (lower) GUS staining; bars: 1 cm [Reproduced from Song and Sink (2006a)]

To date, there has been no information yet available on field evaluation of transgenic cherry plants.

2.2.5 Strategies for cherry improvement through genetic transformation

Due possibly to emphasis on devising efficient transformation protocols, few reports have yet focused on cherry improvement by introducing novel useful traits. Transformation of the nondisarmed pRi1855 T-DNA yielded the expected dwarf characteristic in the rootstock “Colt”, and was further expected to reduce canopy growth of sweet cherry grafted onto it (Gutiérrez-Pesce *et al.*, 1998; Gutiérrez-Pesce and Rugini, 2004). To obtain cold resistance, the antifreeze protein gene (*afp*) was transformed into a sweet-sour cherry hybrid “Black Eagle” (Dolgov, 1999). One transgenic line was PCR positive for *afp*; however, the expected characteristic, cold resistance, was not expressed

(Dolgov, 1999). Transformation systems for two cherry genotypes have been established and are now transferring several virus-resistant genes into them (Sink and Song, personal communication).

3. FUTURE ROAD MAP

Industry input on possible biotechnology needs was obtained at the Cherry Marketing Committee meeting, Hart, Michigan in June 2001. Next, interviews were held (by K. Sink) with pertinent Michigan State University scientists to gain their perspective on the status of the suggested priorities and possible transgenes. Subsequently, the priorities were reviewed and updated at the 2006 Art Mitchell Symposium (<http://mitchellsymposium.org>).

These priorities will include the most important target traits to be addressed in near future and those are delineated below.

3.1 Diseases

3.1.1 Cherry leaf spot

This disease is prominent throughout cherry-producing regions worldwide and currently is controlled with fungicides (Wharton *et al.*, 2003). These authors tested sour cherry cultivars for resistance, but only the seedlings of “Almaz” (o.p.) were resistant. Attempts to transfer this resistance by traditional breeding to sour cherry are underway. It has been suggested to test *NPRI* homologs, since the homolog *MpNPRI* from *Malus* was used to confer fire blight resistance in apple (Malnoy *et al.*, 2004). It may be easy to isolate a similar homologous gene from cherry and test it. Otherwise, no genes specific for resistance to this pathogen have been isolated.

3.1.2 Armillaria

Three species, *mellea*, *ostoyae* (more virulent in northern Michigan), and *bulbosa* are involved. This root rot is mostly a problem for cherry production in Michigan, though it affects other stone fruits in many production regions (Beckman and Lang, 2004). An extensive screening of *Prunus* spp. and rootstocks is underway (Lang, personal communication). No resistance genes have yet been reported.

3.1.3 Brown rot

Monilinia fructicola (G. Wint.) Honey (Ogawa *et al.*, 1995) and *Monilia laxa* (Aderhold and Ruhland) Honey cause blight on twigs and blossoms, cankers, and fruit rot. The problem is worldwide, with sweet cherry generally more sensitive than sour cherry. Cultural practices and fungicides are used for control. No genes directly involved are yet available via breeding or genomics.

3.1.4 Cherry yellows

This disease is a complex of at least two viruses, PDV and PNRSV (Vasková *et al.*, 2001). Even when planting stock is virus free, the virus can be transmitted via infected pollen; thus, flowers often are removed from young trees to prevent infection

during tree establishment. Although the viruses usually are not lethal, annual GA₃ applications may be required later to reduce the symptoms of leaf and bud chlorosis, and increase yield by about 30% over nontreated infected trees. There is no control for this disease once trees are infected. Gene sequences, in PTRAP6i, are available for both viruses (Liu, 2005). But, variants of these viruses exist (Ogawa *et al.*, 1995). A proof of concept for the virus resistance crossing a graft union is underway at MSU using RNA interference (RNAi) technology.

3.1.5 Bacterial canker

This disease is incited by *Pseudomonas syringae* pv. *syringae* van Hall and *P. s.* pv. *morsprunorum* (Wormald) Young *et al.*, causing cankers on limbs, branches, and trunks as well as spots on leaves and fruit, and flower blast and spur death at bloom (Ogawa *et al.*, 1995). Bacterial canker is a limiting factor for tree survival in some regions and can be a significant problem in most. The disease is most prevalent on sweet cherry: “Royal Ann”, “Bing”, “Lambert”, and “Van” are very susceptible, while “Corum”, “Sam”, and “Sue” appear to have reasonable tolerance to canker. Use of copper compounds for control is limited due to the development of resistant strains. Promising strategies may be to test lytic proteins, *hrp*, and *NPRI* genes similar for resistance to fire blight.

3.1.6 Powdery mildew

The dominant gene *Pmr1* for cherry powdery mildew resistance has been reported (Olmstead and Lang, 2002). If this gene could be isolated and cloned, the possibility would exist to transfer it to sensitive commercial sweet cherry cultivars like “Bing”, “Rainier”, and “Lapins.”

3.2 Insects

3.2.1 Plum curculio

This beetle lays eggs under the fruit skin, and larvae eat the fruit flesh, leaving an ugly crescent-shaped mark (<http://www.msue.msu.edu/vanburen/plumcurc.htm>). There is zero tolerance for the

insect. Control is considered difficult and more so because the availability of organophosphate pesticides may be in jeopardy in the United States by the Food Quality Protection Act. No target genes are presently available.

3.2.2 Cherry fruit fly (CFF)

There are two fruit flies on cherry in the eastern US, the Eastern fruit fly (*Rhagoletis cingulata* Loew) (Compton *et al.*, 2005) and the Black CFF (*Rhagoletis fausta* Osten Sacken) (<http://pesp.org/mcc98-final.htm>). The Western CFF (*Rhagoletis indifferens* Curran) (Smith, 2005) is the major insect pest in the Pacific Northwest. There is zero tolerance for all fruit flies. CFFs lay their eggs under the fruit skin, so larvae hatch already in the flesh. Insecticides must be ingested by the adult for control, since contact insecticides are not allowed. These insects are a more widespread threat than plum curculio, since they occur later in the growing season when pesticide residues can be a problem due to multiple applications. A possible control approach may be via pheromone engineering to change the host attractiveness, a scheme that would mimic the natural host marking system. No breeding attack or transgene(s) are presently possible.

3.3 Chilling and Freezing of Flowers

In *Prunus* spp., the pistil is susceptible to freezing spring temperatures. This results in flower losses and concomitant reduced yields. In sour cherry, fluctuating annual yields are due largely to this factor. Sour cherry has good cold acclimation in all tissues but the pistil and a cherry homolog of the *CBF1* gene has been found (Owens *et al.*, 2002). Further expression studies are needed. Suggested gene constructs to test include pistil promoters *SK2* and *PsTLL1* in conjunction with *CBF* genes.

3.4 Fruit Traits

3.4.1 Pitless fruit

The hard cherry pit can escape detection during processing and wind up damaging the teeth of the

consumer. The cherry fruit is a drupe, having an ovary that is composed of the exocarp, mesocarp, and endocarp (the pit containing the embryo). The pit is more precisely the outer portion of the endocarp where the cells become highly lignified and thickened during development as the fruit matures. The pit is about 4–5 mm, and some varieties may have a small tip at the pit base that may break off during processing, but this is not a problem with “Montmorency.” The developing embryo promotes growth of the developing fruit. At the end of stage II, the embryo is fully developed and subsequently extensive fruit enlargement takes place. If the promoter of the endocarp lignification genes could be discovered, it may be possible to pursue a change to a softer endocarp. The embryo is soft and could be considered edible, so that if pits break or escape during processing, it would not be the problem of present. No soft pit mutants have been found for any stone fruit crop. Almonds have varying degrees of pit strength, but no soft-pit almonds that can be eaten are known. Although genes involved in lignification are probably in current EST libraries, the problem is probably more complex and problematic to solve using transgenes.

3.4.2 Firmer cherry fruit at harvest

Although sour cherries generally have high-quality fruit at harvest, the shaking process, conveyer belt, and bulk handling all lead to bruising of the fruit. Wind whipping of fruit on trees also causes bruising. Some Michigan cherry orchards have a problem with unusually soft fruit most years, whereas soft fruit occurs less frequently in other orchards. This is complicated by the fact that there may be sport clones of “Montmorency”, and an environmental interaction may play a role. In the western United States, GA₃ is applied to increase sweet cherry fruit firmness. Similar GA₃ tests have been undertaken on sour cherries in Michigan. Thus, transgene GAs may be of interest with fruit-specific promoters. No single gene/enzyme is likely to significantly impact texture (firmness). Such genes are likely to function in concert with additional factors (Giovannoni, 2001). The gene expansion may represent a candidate that could be tested immediately. For polygalacturonases, which

are highly redundant among species, knock-out technology may not have the desired effect.

3.4.3 Browning of bruised flesh

Elimination of bruise-induced flesh browning in either sweet or sour cherry would be desirable. A transgenic approach would be through knock-out or antisense control of the enzyme polyphenol oxidase, coupled to a fruit promoter.

3.4.4 Red fruit flesh

The ripe fruit of “Montmorency” have a red skin, but clear flesh. “Montmorency” also has a high level of melatonin, a desirable component in cherry juice. “Balaton” has red color throughout the fruit, but a lower level of melatonin. Although some genes for anthocyanin are available, a transgenic “Montmorency” having red fruit and red flesh, produced strictly for juice, probably would not be a profitable venture.

ACKNOWLEDGMENTS

The authors thank Rebecca Baughan for assistance in the preparation of this manuscript.

1. INTRODUCTION

1.1 Origin of Grapevine and the History of Viticulture

The domestication of grapevine (*Vitis vinifera* L.) is closely linked to the discovery of wine that was considered by ancient cultures as a gift from the Gods. The mythology of wine and its mystical significance has given the grapevine a privileged position among cultivated plants and the growing of grapes has a prominent place in the history of western civilization (Johnson, 1989). Although wild grapes were present in many places of Eurasia during the Neolithic period, it is generally considered that cultivation of the grapevine existed by 6000–5000 BC along the eastern shores of the Black Sea in the region known as Transcaucasia where the greatest genetic diversity is found and very early archaeological evidence, including grape pips and artefacts of a “wine culture” were excavated (Zohary, 1995; McGovern, 2003). Uncertainty remains about the occurrence of a secondary domestication center in western Mediterranean (Grassi *et al.*, 2003; Arroyo-Garcia *et al.*, 2006; Imazio *et al.*, 2006) with paleobotanical findings in Spain dated 3000 BC (Nunez and Walker, 1989). The genetic relationship between wild and cultivated grapes is still not resolved but progress is being made using nuclear and plastid DNA markers (Perret *et al.*,

2000; This *et al.*, 2001, 2006; Sefc *et al.*, 2003; Carreno *et al.*, 2004).

By 4000–2000 BC grape growing extended to Asia Minor, through the Fertile Crescent, into the Nile delta, and Balkan Peninsula. During the 1st millennium BC, the Phoenicians and Greeks introduced viticulture into the western Mediterranean (McGovern, 2003). It is likely that cultivated grapes were also brought to China from Asia Minor during the Han Dynasty (200 BC) but the cultivation of grapevine is historically proven in Japan only from 1200 AD. Under the influence of Rome, the growing of grapes extended throughout Europe from the shores of the Atlantic to the valleys of the Rhine and the Danube despite the edict of the Emperor Domitian (92 AD) to limit the growth of provincial viticulture and to protect the export of wine from Italy. With the fall of the Roman Empire the wine trade and grape growing went into decline, but the spread of Christianity to northern Europe and the need for wine for sacramental purposes led to the establishment of a new international trade in wine (Johnson, 1989).

By 600 AD the consumption of wine had been prohibited under Islamic law and this promoted the cultivation of table grapes in the Middle East and North Africa. This led to the introduction of table grapes into Spain, from where they spread to France, Italy, and the New World. The restoration of wine grape cultivation in North Africa did not

occur until the colonization of Algeria by the French in 1830.

By the end of the Middle Ages, wine drinking was a firmly established social custom over most of Europe, and viticulture grew steadily from the 16th to the 19th centuries despite a series of calamities such as the frost of 1709 and the phylloxera plague, which appeared in France in 1868 and then spread progressively through all the grape-growing regions of Europe (Johnson, 1989).

In 1525, Cortez ordered the planting of grapevine in Mexico and by 1550 the growing of grapes had spread to Peru, Chile, and Argentina. In 1616, viticulture started in South Africa by Dutch settlers at the Cape of Good Hope. The first grapes were planted in California in 1697 and the development of viticulture extended with the establishment of numerous Spanish missions from 1769 to 1810. Immigration played a large part in the development of commercial viticulture in California during the second half of the 19th century. Viticulture in Australia began in 1788 with the founding of a penal colony. In the 1850s German Lutherans founded the wine industry of the Barossa Valley and at the end of the 19th century, settlements were established along the Murray River in South Australia and Victoria and the growing of grapes for drying became the predominant industry of this region. In New Zealand, grapes were planted early in the 19th century by French settlers and religious orders (Johnson, 1989).

1.2 Diversity, Taxonomy, and Evolution of Grapevine

The cultivated vine (*V. vinifera* L.) belongs to the family Vitaceae that is primarily intertropical in its distribution and consists of perennial plants that take the form of woody or herbaceous liana (tree-climbing plants) or shrubs with lianalike stems. The family shows considerable morphological variability and a large range of adaptation to highly varied environments. The systematics of the Vitaceae is based on the classification of Planchon (1887) who identified 10 genera. After many revisions, the family currently consists of 17 genera from which only the genus *Vitis* produces edible fruit. Until recently, Vitaceae were included with the Rhamnaceae

and Leeaceae in the Rhamnales order within the Eudicots classification. Improved classification is expected to occur over time as more molecular information becomes available. The taxonomy browser at National Center for Biotechnology Information (NCBI) currently lists the Vitaceae as a core eudicotyledon in the order Vitales (<http://www.ncbi.nlm.nih.gov/Taxonomy>).

According to cytotaxonomy studies (Shetty, 1959; Lavie, 1970), the family ancestor may belong to the *Cissus* genus (367 species) that is typically intertropical, distributed throughout Africa and Asia, and consists of plants with tetramerous flowers and a chromosome karyotype of $2n = 24$. The genera *Cyphostemma* (258 sp.) and *Tetrastigma* (132 sp.) occur respectively in Africa and Asia and appear to be closely related. They have morphological and anatomical similarities and a common karyotype ($2n = 22$) with many cases of polyploidy. The genera *Ampelocissus* (90 sp.), *Vitis* (71 sp.), *Ampelopsis* (31 sp.), and *Parthenocissus* (18 sp.) consist of plants with pentamerous flowers and a common karyotype of $2n = 40$, with the exception of *Vitis* ($2n = 38$). They are distributed in the temperate climates of America, Asia, and Europe, with the exception of *Ampelocissus* that is typically found in the tropical warm areas including Africa. The number of species indicated in brackets for each genus corresponds to a compilation of the references found in the literature (J.-M. Boursiquot, personal communication). Due to problems of synonyms, the numbers may be overestimated).

Phylogenetic studies based on the study of chloroplast DNA confirmed the relationships of Vitaceae and Leeaceae (nonclimbing vines), but showed that these two families were distant from the Rhamnaceae and close to the base of the large clade of Rosids (Savolainen *et al.*, 2000; Soltis *et al.*, 2000). Other studies dealing specifically with the Vitaceae (Ingrouille *et al.*, 2002; Soejima and Weng, 2006) suggest that these became separated from the Rosids at the end of the Cretaceous period about 100 million years ago (mya) and confirm the ancestral character of *Cissus* and the closeness of *Cyphostemma* and *Tetrastigma*, forming a large clade including also the genus *Cayratia* (65 sp.), which had already been previously claimed (Rossetto *et al.*, 2002). The recent completed sequencing of the grapevine chloroplast genome has placed the Vitaceae as sister to the other

rosids (Jansen *et al.*, 2006). Among the Vitaceae with $2n = 40$ chromosomes, the *Ampelopsis* genus would be ancestral, the genera *Parthenocissus* and *Ampelocissus* would be intermediary, and the *Vitis* genus, including the subgenera *Euvitis* ($2n = 38$) and *Muscadinia* ($2n = 40$), would be more recent.

The hypothesis that *Ampelopsis* may be older than *Parthenocissus* and *Vitis* is supported by the work of Lodhi and Reisch (1995), who observed that the nuclear genome of *Ampelopsis brevipedunculata* is made up of 666 Mpb (mega base pair), which is significantly higher than the genome of *Parthenocissus tricuspidata* (516 Mpb) and the average in the species of *Vitis* (475 Mpb). Throughout a diverse range of organisms, retrotransposon copy number appears to be correlated with genome size. When active, these elements play a role in genetic evolution with replication and insertion increasing genome size and creating polymorphisms (Bennetzen, 2000). Several retrotransposons have been identified in *V. vinifera* (Verriès *et al.*, 2000; Pelsy and Merdinoglu, 2002; Kobayashi *et al.*, 2004). The level of retrotransposons in the genome was estimated to be 41% (Tomkins *et al.*, 2001) and it is likely they have played a considerable role in the evolution of the Vitaceae family.

The phylogenetic distance between *Vitis* and *Ampelopsis* shown by cladistic analysis practically nullifies any hopes of genetic hybridization between these two genera by conventional breeding. The same is probably true for hybrid production between *Vitis* and *Parthenocissus* species. The use of genetic resources from "Virginia creepers" therefore lies in the development of somatic hybridization methods using protoplast technology. However, this technique is a long way from being mastered in vines, despite some success in the regeneration of protoplasts from somatic embryos (Reustle *et al.*, 1995).

Conversely, the phylogenetic proximity of the subgenera *Euvitis* and *Muscadinia* explains why the karyotype differences have not been an insuperable obstacle in crossings between *V. vinifera* and *V. rotundifolia* (Wylie, 1871; Detjen, 1919; Dunstan, 1962; Olmo, 1971; Bouquet, 1980). Given its anatomical, morphological, and karyological characteristics, the subgenus *Muscadinia* must be elevated to the genera level as proposed one century ago by Small (1903), though this proposal has not yet achieved general acceptance.

Although there is no doubt about the close phylogenetic relationship between *Euvitis* and *Muscadinia*, the hypothesis of a relatively recent origin of the genus and its resulting division into two subgenera, is weakened by the discovery of fossil pips in 55-million-year-old northern European tertiary sediments. Some seeds (*Vitis rectisulcata*) are globular with a smooth chalaza, similar to the pips of the actual *Euvitis* and others (*V. longisulcata*) are oblong with a wrinkled chalaza, similar to the pips of the actual *Muscadinia* (Fairon-Demaret and Smith, 2002). These recent findings confirm the distinction of two types (*Vitis teutonica* and *Vitis ludwigii*) made in 1939 by Kircheimer (cited by Rives, 1975) between fossilized pips assignable to *Vitis* and suggest that the genus *Vitis* was widely distributed throughout the northern hemisphere before the advent of the ice ages. The separation of *Euvitis* and *Muscadinia* may date from the Tertiary period and it is probable that *Muscadinia* became extinct in Europe during the Quaternary. *Muscadinia* could be regarded as transitional between *Vitis*, which are adapted to temperate climates, and *Ampelocissus*, which are adapted to tropical climates (Mullins *et al.*, 1992). *Ampelocissus* has marked similarities in morphology, anatomy, and karyotype with *Vitis* and *Muscadinia* but its ability to hybridize with them is unknown.

The *Muscadinia* is currently represented by only three species (*V. rotundifolia*, *V. munsoniana*, and *V. popenoei*) of which only the first two have been properly described and whose natural range is limited to the Southeast of the United States. Cytological observations relating to F_1 hybrids *V. vinifera* \times *V. rotundifolia* could lead to the assumption of an allo-polyploid origin of the vine (Patel and Olmo, 1955). However, this hypothesis has not yet been confirmed either by *in situ* hybridization results from *V. vinifera* chromosomes, which have only revealed a single ribosomal (5.8S, 18S, and 26S rRNA) locus (Haas *et al.*, 1994; Haas and Alleweldt, 2000), or by the data acquired during development of genetics maps. If an auto- or allo-polyploidization process really occurred, then there is no doubt that it was very old and followed by many rearrangements. Unexplained is why the *Muscadinia*, apparently widely scattered across the entire northern hemisphere during the tertiary, did not become diversified like the *Euvitis* and

had a considerably reduced natural range during the quaternary eventually becoming limited to the North American continent.

The genus *Vitis*, formerly *Vitis* subgenus *Euvitis* Planch., contains about 70 species. These are found mainly in the temperate zones of the northern hemisphere and are distributed almost equally between America and Asia. Only one species, *V. vinifera* L., originated in Eurasia. It has been spread throughout the world by man. The systematics of *Vitis* has been a subject of controversy for more than a century. The determination of the number of “real” species of grapes, and their proper names, has considerable significance for plant improvement. So far, the most comprehensive treatment of the genus is that of Galet (1967) who listed 59 species, including 25 species from Asia, grouped into 11 series (Mullins *et al.*, 1992).

Many species of *Euvitis* are thought to have arisen during the Quaternary ice ages. Their distribution is consistent with the breaking up of large populations by the ice fronts and the survival of small populations in refuges. This isolation and differing environmental conditions of the refuges provided ideal circumstances for speciation. The formation and dissolution of refuges probably occurred several times during the Quaternary period. At the end of the ice ages, the species of *Euvitis* acquired a remarkable diversity in morphological and physiological characters, but this was not associated with significant genetic differentiation. There are no genetic barriers and the species of *Euvitis* are interfertile. They are really ecospecies and can be defined as populations of grapevines that are easily distinguishable by morphological characters and which were/are isolated by geographical, ecological, and phenological barriers (Mullins *et al.*, 1992).

The high sensitivity of *V. vinifera* to many pests and pathogens has hampered its universal cultivation since the 19th century and led particularly to the domestication of wild species in the United States, *Vitis labrusca* in the Northeast (Hedrick, 1908) and *V. rotundifolia* in the Southeast (Olien, 1990). There is no doubt about the native origin of the *Muscadinia* grapevines. But it is a practical certainty that the *labrusca* varieties, and notably the Concord variety, are natural hybrids between this wild species and the varieties of *V. vinifera* introduced in

the first colonies (Booth, 1911; Tukey, 1966). Due to their hybrid origin, these varieties were named “*Vitis × labruscana*” by Galet (1967).

There is considerable diversity within *V. vinifera*. The number of different varieties held in germplasm collections around the world is estimated at approximately 10 000 (Alleweldt and Dettweiler, 1994) but an accurate knowledge of this diversity is hampered by a complex synonymy. The same variety may have different names and different varieties may have the same name. However, there is a general acceptance that the number of “real” varieties properly identified in the world is closer to 5000. Included are cultivars that are widely grown in many grape growing countries, those that are of strictly local importance and those which have practically disappeared from vineyards. The classical method of ampelography based on morphological descriptions to distinguish cultivars is now nearly completely replaced by the use of molecular markers, especially the microsatellite DNA markers (Thomas and Scott, 1993; Thomas *et al.*, 1993, 1994; Dangl *et al.*, 2001; This *et al.*, 2004) coupled with computer technology.

1.3 Economic Importance

Grape berries are eaten fresh (table grapes) or dried (raisins), but the main use is wine making. Total world grape production in 2005 was estimated at 66 million tons, from which 65.7% was used for wine production estimated to be 277 million hectoliters, 26.7% consumed as table grapes, and 7% transformed into raisins. The worldwide surface area of vineyards was estimated to be 8 million hectares distributed between Europe (58.9%), Asia (21.7%), America (12.1%), Africa (4.9%), and Oceania (2.4%) (Organisation of Viticulture and Wine (OIV) Statistics 2005).

In 2005, the 10 highest wine producing countries were Italy (50.6 million hectoliters), France (50.5 million hectoliters), Spain (35.3 million hectoliters), the United States, Argentina, Australia, China, Germany, South Africa, and Chile. The main consumers of wine are the wine-producing countries, but during the last 50 years, there has been a marked and continuous drop in consumption in many of the traditional wine-drinking nations. In France, for example, consumption per capita was 1271 in 1963, 741

in 1988, and 531 in 2005. This gap between production and consumption has been offset to some extent by an increase of wine consumption in northern European countries, the United States and China, as well as the growing international trade in wine. In 2005, 28.9% of world wine production was exported with the three leading wine-producing countries responsible for half of all exports.

In some countries large quantities of wine are distilled to produce high-proof spirits (cognac, armagnac, brandy, or grappa) and fortifying spirits for the making of sherry, port, dessert wines, or other aperitif beverages. Since the “French paradox” was brought to the fore (Renaud and De Lorgeril, 1992), there is epidemiological and biological evidence that moderate consumption of wine protects against cardiovascular diseases (Rotondo and Gaetano, 2000). Recently, the discovery of melatonin in berries of several cultivars suggests that the well-established pharmacological properties of the grapevine are due not only to the presence of polyphenolic compounds, such as resveratrol, anthocyanins, and proanthocyanidins, but also to the powerful antioxidant activity of this compound (Iriti *et al.*, 2006). While the negative impacts of excessive alcohol consumption have been well documented, research into the nutritional value and health benefits of wine and grape products are relatively new study areas.

It is difficult to state precisely the worldwide production of table grapes. Certain producing countries do not provide statistics and others are hampered in their efforts because of indifferent reporting from individual producers. Summarizing 2003 OIV statistics, Asia has the highest production, with China as leading country (3.4 million tons), followed by Turkey (1.5 million tons), Iran (1.4 million tons) and India (1 million tons). In America, table grapes are produced mainly in Chile (0.9 million tons), the United States (0.7 million tons), and Brazil (0.6 million tons). In Europe, table grapes are produced mainly in Italy (1.5 million tons) and Spain (0.7 million tons). In Africa table grapes are produced mainly in Egypt (1 million tons). Despite the perishability of the fruit and the high cost of transportation, table grapes support a significant international trade with 2.9 million tons imports (mainly into United States, Germany, Russia,

and the United Kingdom) and 3.1 million tons exports (mainly from Chile and Italy). Annual per capita consumption of table grapes is low and does not exceed 10 kg in most producing countries. In Europe and North America table grapes represent less than 5% of annual per capita consumption of fresh fruits. Fresh grapes have important nutritional qualities. They provide about 700 cal kg⁻¹ and in addition contain calcium, phosphorous, and vitamins.

For raisins (OIV 2005 statistics), the world's largest producers are Turkey with a production of nearly 3.4 million quintals, the United States (3.2 million quintals), and Iran (2.1 million quintals). Raisins are a high-energy food, rich in sugars providing 3340 cal kg⁻¹.

Grape berries have many other uses, such as canned fruit after pasteurization. The fresh juice of pressed grapes can be bottled for consumption, converted to jellied products or concentrated (such as the “*pecmez*” of Turkey). In addition there are many industrial and miscellaneous uses of grapes and grape products including the production of ethanol, wine vinegar, grape-seed oil, anthocyanin pigment, food additives, cosmetics, or pharmaceuticals. Finally the residues of wine making (marcs) can be processed for the industrial production of tartaric acid and the waste can be further utilized for fertilizer production.

1.4 Traditional Breeding: Objectives, Constraints, Tools, and Strategies

The breeding of woody perennial fruit plants, such as grapevines, presents considerable difficulties. Although cultivated grapes bear self-fertile flowers, they do not breed true from seed. In their wild state, all the species of *Vitis* (including *V. vinifera*) are dioecious resulting in strict allogamy that maintained a high level of individual genetic heterozygosity. The heterozygosity of cultivated grapes was confirmed by DNA microsatellite analysis (Thomas and Scott, 1993; Sefc *et al.*, 2000) and recently by single nucleotide polymorphism (SNP) markers (Salmaso *et al.*, 2004). The lower level of heterozygosity observed in the remaining wild grapevines (Aradhya *et al.*, 2003) may be attributed to some inbreeding existing in small and isolated populations. Grapevine cultivars represent gene combinations that are disrupted by

the sexual process and the fixed heterozygous state of cultivars have been maintained and perpetuated for centuries by vegetative propagation. Thus, modern wine production is based primarily on traditional cultivars. The styles of wine produced by these cultivars enjoy a high level of consumer acceptance with marketing focused on traditional cultivars. Appropriate management technologies have been developed to grow these traditional cultivars, and they have become firmly entrenched by custom or by law in some European countries and regions effectively limiting what cultivar can be grown in specific regions. As a consequence of these special circumstances, clonal selection, the exploitation of genetic variation within traditional cultivars, has become the most widely used procedure for improvement of wine grapes.

Most wine grapes are of ancient origin and are thought to have arisen from natural crosses within *V. vinifera*. These cultivars might be a mixture of more than one genotype, due to propagation of closely related and phenotypically similar plants. This concept is known as the polyclonal origin of grapes (Rives, 1961). However, molecular analysis based on random amplified polymorphic DNA (RAPD) markers did not detect genetic polymorphism among different clones of Pinot noir despite this phenotypically heterogeneous cultivar being grown since the early Middle Ages (Ye *et al.*, 1998). Whatever their origin, grapevine cultivars are likely to have accumulated by now a substantial amount of somatic mutations (Franks *et al.*, 2002). These are more difficult to detect using molecular markers, but amplified fragment length polymorphism (AFLP) techniques (Scott *et al.*, 2000), microsatellites (Franks *et al.*, 2002; Riaz *et al.*, 2002), or more recent techniques based on retrotransposons (Pelsy *et al.*, 2003) and SNPs (Salmaso *et al.*, 2004) now make it possible to detect genetic polymorphism derived from mutations among clones of the same variety. Though the selection of bud sports has been an important element in genetic improvement of pome and stone fruits, the occurrence of such bud sports is less well documented in grapes, except for some visual mutants (Boss and Thomas, 2002; Franks *et al.*, 2002; Fernandez *et al.*, 2006; Walker *et al.*, 2006). A considerable amount of work has been done for the generation of mutants in fruit crops, mostly using combinations of radiation and tissue culture techniques (Predieri, 2001) but

results on grapevine are few. Moreover, most of the expected mutations are usually recessive and are only revealed in the M₂ generation, which can take several years for grapevine.

Efficient tools for genetic mapping have been developed during the last 10 years and are now used for the studying the genetics of important traits. In 1998, the international scientific community decided to join its effort to develop a large set of microsatellite (= simple sequence repeat, SSR) markers through a consortium, the Vitis Microsatellite Consortium (Adam-Blondon *et al.*, 2004; This *et al.*, 2004; Merdinoglu *et al.*, 2005). Since Lodhi *et al.* (1995), several genetic linkage maps have been published for grape (for a review, see Adam-Blondon *et al.*, 2007; Riaz *et al.*, 2006). Recently, in the framework of the International Grape Genome Program (<http://www.vitaceae.org>) an integrated SSR map was constructed using segregation data from five full-sib progenies (Doligez *et al.*, 2006a). This consensus map, comprising 502 SSR loci has a total length of 1647 cm (Kosambi) covering the 19 linkage groups. Physical maps are under construction and will greatly facilitate the mapping of genes and candidate gene approaches through their integration with genetic maps (Lamoureux *et al.*, 2006). Several bacterial artificial chromosome (BAC) libraries are now available in grape, opening the road for structural genomics in this species (Tomkins *et al.*, 2001; Adam-Blondon *et al.*, 2005, 2007). Expressed sequence tag (EST) sequencing projects have provided a basic resource for the study of the molecular mechanisms involved in most of the traits of interest of the grapevine (Ablett *et al.*, 2000; Goes da Silva *et al.*, 2005; Terrier *et al.*, 2005) but also for an efficient transfer of knowledge from model species to grapevine. Over 400 000 sequences, mostly ESTs, have been deposited at NCBI (<http://www.ncbi.nlm.nih.gov>) corresponding to more than 16 000 UniGenes (Build #19; <http://www.ncbi.nlm.nih.gov/UniGene/UGOrg.cgi?TAXID=29760>) or more than 34 000 unique sequences as determined by the DFCI grape gene index (Release 5; <http://compbio.dfci.harvard.edu/tgi/cgi-bin/tgi/gimain.pl?gudb=grape>) Recently, grape berry biochemistry was investigated using proteomic analysis (Sarry *et al.*, 2004).

Two grape genome DNA sequencing projects are being undertaken. One is conducted at IASMA (Italy) and involves the sequencing of the Pinot Noir genome (Velasco *et al.*, 2006). The second project conducted at Genoscope in collaboration with URGV (France), is based on a near-homozygous line PN40024 (Bronner and Oliveira, 1990) that has Pinot Noir as one parent. This project is also associated with the genome sequencing of grape pathogens. The availability of the sequence of a pathogen and of its host would offer many opportunities to understand the molecular mechanisms underlying the dynamics of host–pathogen interactions.
